There is an acute shortage of accommodation for maternity cases in several areas in Yorkshire in both private and municipal institutions. Leeds Maternity Home has had to refuse bookings for 400 cases during the last 3 months; and all its beds are taken for 2 or 3 months ahead. Among the steps being taken to meet the situation are the opening of 50 to 80 beds at St. Mary's Infirmary, Leeds, the adaptation of three wards at the Staincliffe County Hospital, and the establishment of a maternity unit at Otley County Hospital. The reasons for the shortage are given as the increased population of the cities, the greater demand for institutional confinement (Halifax General Hospital had 1,200 maternity cases last year), and the fact that beds are still kept for air-raid casualties.

An Association for the Advancement of Psychoanalysis has recently been founded in New York.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

LETTERS, NOTES, ETC.

Control of Venereal Disease

Dr. LENNOX JOHNSTON writes: The suggestion implicit in Dr Margaret Rorke's letter (Jan. 9, p. 53) of the desirability of re-educating the public about venereal disease and sex is, I think, supported by a case which has come to my notice. The patient, a man of about 35 who had contracted syphilis, committed suicide. Patients at the treatment centre became aware of his complaint, and in this way his fellow-workmen also knew what was wrong with him, and accordingly their attitude underwent a change which hurt him deeply. This, I believe, was largely responsible for his suicide. I think that education on sex and venereal disease would best be carried out over the wireless. Weekly talks by medical psychologists on the many practical problems connected with sex, and occasional talks on venereal disease, would quickly take from sexuality the shame and guilt with which, owing principally to the taboo, it is so often associated, and which are the underlying psychological barriers to the adequate control and treatment of venereal disease.

Medical Aspects of Workmen's Compensation

Dr. G. F. WALKER (Peterborough) writes: The review of Dr. Jordan's book (Jan. 2, p. 13) contains two statements which cannot be allowed to pass without comment. Your reviewer states that no volume similar to this has yet been written or published in the United Kingdom. May I draw attention to the fact that my own book, *The Injured Workman*, was published in Bristol in 1933. There are, of course, several other books quite well known to those familiar with workmen's compensation and all written and published in the United Kingdom. Your reviewer's second proposition that the medical profession have not hitherto regarded workmen's compensation as important is almost too naive to be dealt with.

Safe Milk and Milk Products

Dr. WILLIAM HUNTER (Newcastle-upon-Tyne) writes: Following the plea of Dr. Arthur G. Watkins (Jan. 30, p. 140) for a safe milk supply, and looking ahead, may I suggest that steps should also be taken to ensure that milk products, such as butter, cream, ice cream, and cheese, will also be made to conform with reasonable standards of cleanliness and safety.

Disclaimer

Dr. A. KERR CLARKSON wishes to emphasize that the statement attributed to him in press reports of a lecture he gave on accident prevention to the Industrial Welfare Society recently is entirely incorrect.

HAEMOGLOBINOMETRY AND THE USE OF THE HAEMATOCRIT

A REPORT TO THE TRAUMATIC SHOCK COMMITTEE OF THE MEDICAL RESEARCH COUNCIL

[The Committee on Traumatic Shock, appointed by the Medical Research Council, recently nominated a Subcommittee on Analytical Methods to advise, among other things, on methods for estimating haemoglobin and on the use of the haematocrit. The Subcommittee was asked to consider the estimation of haemoglobin both from the point of view of accurate haemoglobinometry, and from that of the standardization of one of the rapid methods commonly employed for clinical use. In the report which follows these two aspects of the problem are dealt with under separate headings.]

I. THE PRESENT STATE OF UNCERTAINTY IN ACCURATE HAEMOGLOBINOMETRY

A. Haemoglobin Chemistry

To make clear the difficulties of accurate haemoglobin estimation a short statement of what is at present known about haemoglobin chemistry is necessary.

In the venous blood of normal men haemoglobin exists mainly in two forms—oxyhaemoglobin (O_2-Hb) and reduced haemoglobin (Hb). The ferrous iron of Hb and O_2-Hb may be oxidized *in vivo* and *in vitro* to ferric iron, to form methaemoglobin (met-Hb) (Conant and Pappenheimer, 1932; Conant, 1933). It is probable that small quantities of met-Hb (not infrequently 2 to 3% and occasionally as much as 10% of the total haemoglobin) also exist in the blood of some normal persons (Ammundsen, 1941). Carbon monoxide forms an additive compound with haemoglobin, for which it has about 210 times the affinity of oxygen. Small quantities (e.g., 1 to 3%) of carboxyhaemoglobin (CO-Hb) may be formed in the bloods of normal men exposed to very small concentrations of CO—e.g., city dwellers and smokers. CO-Hb and met-Hb cannot carry oxygen to the tissues, but can be transformed relatively easily into Hb in the body. It is possible that small quantities of other forms of "inactive" haemoglobin (i.e., haemoglobin which does not transport oxygen) exist in normal blood.

In the blood of men suffering from certain poisons and intoxications larger amounts of "inactive" haemoglobin may be present. For instance, in those poisoned with CO 20 to 50% of the total haemoglobin may be CO-Hb (Peters and van Slyke, 1931a). During treatment with certain drugs (e.g., phenacetin, sulphanilamide) appreciable quantities of met-Hb and sulphaemoglobin (S-Hb) may be formed. The bloods of patients given large doses of sulphanilamide not uncommonly show 10% met-Hb, rarely 10% of S-Hb (Harris and Michel, 1939). Very occasionally as much as 30% of the total haemoglobin may be met-Hb. S-Hb, once formed, apparently cannot be changed into "active" haemoglobin *in vivo*; its constitution is unknown. When red cells are ruptured and haemoglobin spills into the plasma methaemalbumin is formed (e.g., in blackwater fever and occasionally after sulphonamide treatment) (Fairley, 1941). It is possible that other forms of "inactive" haemoglobin exist in the bloods of patients.

If haemoglobin is treated with acid or alkali it is split into a brown pigment, haematin, and the protein globin. This brown pigment can be obtained crystalline in the form of its chloride, haemin, and is an iron porphyrin complex (Peters and van Slyke, 1931b). If dissolved in N/10 NaOH and treated with a strong reducing agent it combines with various organic bases to form a series of compounds, haemochromogens, with characteristic absorption spectra. These compounds are unstable, and exist only so long as the action of the reducing agent persists.

B. Methods Employed for Haemoglobin Estimation

(*a*) *Methods Involving Gas Analysis.*—In these the capacities of whole blood for various gases are taken as a measure of haemoglobin. Since methods of purifying, particularly drying, cause a progressive diminution in the gas capacity of haemoglobin, the true gas capacity of unit weight of pure haemoglobin has never been determined, only inferred.

1. The oxygen capacity of the blood may be determined with considerable accuracy by van Slyke's manometric method (Peters and van Slyke, 1932b) and with less accuracy by Haldane's method (Haldane, 1899). This measures only haemoglobin that combines loosely with oxygen.

2. By the former method the CO capacity of blood may be determined with accuracy (Peters and van Slyke, 1932c). This is a measure of Hb, O_2-Hb, and CO-Hb. If the blood is first reduced with sodium hydrosulphite ($Na_2S_2O_4$) and then immediately gassed with CO, met-Hb is transformed into CO-Hb, and is thus also estimated (Peters and van Slyke, 1932d). S-Hb cannot, however, be turned into CO-Hb.

The manometric methods in experienced hands give accurate highly reproducible results, but are not suitable for general use.

(*b*) *Colorimetric Methods.*—All accurate chemical colorimetric estimations are based on matching by eye the colours of sample and standard solutions viewed simultaneously on a photometer head. Errors may arise from inaccurate preparation of solutions, faulty design or use of instrument, or an unsuitable condition of the analyst's eye (Walsh, 1926; Guild, 1932). If such errors are controlled the limit of accuracy depends on the goodness of match of sample and standard colours. All colorimetric estimations need careful checking by some other method of estimation.

In colorimetric estimation of haemoglobin uncertainty arises, first, because it is difficult to be sure that the colours of either sample or standard solutions are those of one form of haemoglobin only. This is best illustrated by an example. In Palmer's method (Palmer, 1918) the colour of a standard solution of CO-Hb is matched with that of a standard dilution of whole blood gassed with CO. If either standard or sample solution contains appreciable quantities of met- or S-Hb uncertainty arises. For the presence of these compounds may alter the colours of such solutions, the matching of such colours may become less certain, and the significance of the match requires to be assessed before accuracy of estimation can be derived from it. Any substances other than haemoglobin which add colour to the dilutions of whole blood used in colorimetric haemoglobin estimations similarly cause uncertainty. For instance, it is claimed that substances in plasma add to the brown colour obtained when sheep's blood is diluted with N/10 HCl (Wu, 1922; Conant and Pappenheimer, 1932).

The second cause of uncertainty in colorimetric estimations of haemoglobin is the difficulty of obtaining standard solutions of sufficient permanence. Because of the complexity of the absorption spectra of haemoglobin and its derivatives (Newcomer, 1919; Drabkin and Austin, 1935) no artificial standard is satisfactory for accurate matching. The most satisfactory form of standard so far described is a dilution of whole blood thoroughly-gassed with CO. (See Section II B.)

The following haemoglobin compounds and derivatives have been used in the "accurate" colorimetric estimation of haemoglobin.

Hb Compound Used	Authors	Comment
Carboxy-haemoglobin	Haldane (1901) Palmer (1918)	Good colour. Most permanent of known Hb compounds, hence good standard 100% for Haldane's haemoglobinometer, recently standardized. Hb, O_2-Hb, and CO-Hb of blood all changed to CO-Hb. If blood first reduced with $Na_2S_2O_4$, met-Hb also to CO-Hb Requires CO gas
Cyan-methaemoglobin	Stadie (1920)	Fairly good colour. Standards keep fairly well but require standardizing by some other method. Hb, O_2-Hb, CO-Hb, and met-Hb all transformed to cyan-met-Hb Requires KCN solution
Acid haematin	Sahli (1931) Newcomer (1919)	Poor colour, taking some hours to develop fully. Standards usually artificial, often unsatisfactory, and require independent standardization. Simplest of methods Substances in plasma may add to colour. Colour probably related to total haemoglobin
Alkali haematin	Wu (1922) Clegg and King (1942)	Poor colour, better by photometric match. Permanent standard of haemin crystals. All Hb compounds, including S-Hb, are turned into alkali haematin. Simple Recent work (Clegg and King, 1942) has shown this method to have considerable promise; it may eventually prove more satisfactory than the Sahli method
Pyridine haemochromogen	Rimington (1942)	Fairly good colour, better by photometric match. Permanent standard of haemin crystals. All haemoglobin compounds changed to haemochromogens Smell of pyridine very unpleasant. All methods require solid $Na_2S_2O_4$, and difficult to be certain if this is effecting complete reduction of haematin
Other haemochromogens	Deutsch (1934)	

As noted above, all colorimetric estimations need careful checking by some other method. Because of the complexity of haemoglobin chemistry, colorimetric estimations of haemoglobin need doubly careful checking.

(c) *Photometric Estimations.*—The basis of all chemical photometric estimation is the matching by the eye of the brightness of two nearly identically coloured fields on a photometer head (Walsh, 1926; Guild, 1932). From this matching the quantity of light of a narrow spectral band that is highly absorbed by the sample solution is estimated. By an independent method of estimation this quantity is related to the concentration of the substance in the sample solution. This method is capable of giving results of a higher reproducibility than many colorimetric estimations. Once checked by an independent method it does not require a standard solution of the sample substance. A high reproducibility of result must not, however, be confused with a high accuracy of result.

In photometric estimations of haemoglobin compounds, apart from errors in solutions, instrument, and in the eye of the analyst, there are two sources of uncertainty. First, there is the difficulty of relating the light absorptions of solutions of whole blood to absolute quantities of haemoglobin. For, supposing the latter be determined (some of the difficulties in this determination have been outlined), unless the whole-blood solutions contain only one form of haemoglobin error may arise. Different haemoglobin compounds have different absorption spectra (Drabkin and Austin, 1935), and thus if there is more than one form of haemoglobin present the total light absorption may not be directly related either to total haemoglobin present or to the amount of the predominant form of haemoglobin. Secondly, any substance that absorbs light of the spectral band used (e.g., other pigments, slight turbidity, slight dirtiness of glass cells) will be estimated as haemoglobin. It may be noted that colorimetric estimations, though often less reproducible than photometric estimations, have the advantage that the eye sees changes of colour from the presence of other pigments and haze from the presence of turbidity.

Hence photometric measurements require considerable care and very careful independent checking to yield accurate results. All the haemoglobin compounds listed under colorimetric methods may be estimated photometrically.

(d) *Photo-electric Methods.*—These again measure or attempt to measure the amount of light of a narrow spectral band absorbed by solutions of pigment, and are subject to the same difficulties as are inherent in photometric measurements. Furthermore, these measurements are dependent on the electrical properties of the photo-electric cells, the design of the electrical circuit of the photo-electric photometer, and the constancy of the light source (Muller, 1939). Precautions must therefore be taken to limit uncertainties from these causes. Again the only certain way is accurate checking by some independent method.

(e) *Iron Estimations.*—In the opinion of this Subcommittee the best available form of check on methods of total haemoglobin estimations is the determination of the iron content of centrifuged solutions of well-washed lysed red cells from defibrinated normal human blood and the relation of this to values obtained by colorimetric or photometric methods. Because of the progressive loss of gas capacity with purification it is difficult to relate this latter or the colour of gas-Hb compounds to the iron content of purified haemoglobin. The Subcommittee prefers the method of titration of ferric iron with titanous sulphate (Klumpp, 1934) to any of the micro-colorimetric methods which have been proposed. Estimations of haemoglobin iron are not without difficulty. Scrupulous precautions to avoid iron contamination from reagents and apparatus must be taken. Since plasma contains small amounts of iron the removal of this must be as complete as possible.

C. Summary

From the foregoing discussion it can be seen that in some of the most commonly used methods of haemoglobin estimation there is uncertainty in what is accurately measured.

Clinically it may be held desirable to know in a patient: (1) the oxygen capacity, (2) the potential oxygen capacity, or (3) the total haemoglobin. The first can only be determined by oxygen capacity estimations. The second at present can only be determined with certainty by the CO capacity of blood first reduced with $Na_2S_2O_4$. The third can only be determined by careful iron estimations. Often there may be little difference between (1), (2), and (3). It is considered that an accurate estimation of (3) would be most practicable and useful in haematology.

II. RECOMMENDATIONS OF STANDARD METHODS FOR CLINICAL DETERMINATION OF HAEMOGLOBIN

Although the conclusion of the preceding section of this report is that there remain fundamental uncertainties which make the accurate determination of haemoglobin impossible at the present time, it is nevertheless thought desirable to suggest certain simple measures of standardization which can be applied to the clinical methods in common use. If the suggestions contained in this section of the report were generally adopted it would at least be possible to compare the results obtained by different workers with a degree of confidence which is certainly not felt at present.

A. Site and Method for obtaining Blood Samples for Estimation

In the opinion of the Subcommittee the best site for taking blood for haemoglobin or R.B.C. volume estimation is a vein, preferably of a warm arm. It is known that blood taken simultaneously from two arm veins may not always have the same haemoglobin content. Therefore, where possible, repeated samples should be taken from the same vein under the same conditions. Blood should be withdrawn with no more than momentary stasis. If skin-prick blood must be used, ear puncture is recommended. The skin of the ear must be perfectly clean and dry. Minute quantities of fluid—e.g., sweat—may cause serious error when 0.02 ml. of blood is pipetted.

B. The Haldane-Gowers Haemoglobinometer

The Subcommittee recommends the Haldane-Gowers haemoglobinometer (Haldane, 1901) for routine haemoglobin measurements. In this instrument 0.02 ml. of blood is gassed with CO and diluted with 0.4% ammonia solution (0.4 ml. liq. ammon. fort. per 100 ml.) (Krogh: Newcomer, 1919) in a standard form of dilution tube till its colour matches that of a standard CO-Hb solution. The amount of dilution is directly proportional to the haemoglobin content.

This instrument has recently been investigated and standardized by a committee formed by the British Standards Institution in conjunction with this Subcommittee, and it is this standard form, B.S. No. 1079–1942 haemoglobinometers (Haldane type), that is recommended. The forms of pipette, dilution tube, and colour tube have been accurately defined. The permissible tolerances on 0.02-ml. pipettes are ±1.5% of marked capacity, on dilution tubes a maximum volumetric error not greater than 1.5% of haemoglobin, on colour standards not more than ±2% about the defined 100% colour. These limits ensure very much greater uniformity than has previously been attained in commercial instruments. The National Physical Laboratory will test pipettes, dilution tubes, and colour standards for conformity with this specification, and will measure the volumes of 0.02-ml. pipettes and the percentage value of the colour standards to the nearest 1%.

Any colour can be matched by mixing varying quantities of red, green, and blue. With suitable precautions it is possible, therefore, to define any colour on a trichromatic scale. The 100% CO-Hb colour accepted for the standard form of instrument has been so defined. The definition was based on measurements made by the N.P.L. on 6 standard glass tubes containing 1 in 100 dilutions of "normal" blood gassed with CO, the oxygen capacity of which before dilution was found by Haldane's method (Haldane, 1899) to be 18.5 volumes %. These standard tubes were prepared by Prof. G. P. Wright. Two ml. of blood freshly drawn from a fasting man was diluted approximately 1 in 100 with distilled water, placed in a 500-ml. glass-stoppered bottle, and copiously gassed with CO prepared from sulphuric and formic acids. A few hours later the haemoglobin solution was again copiously gassed, the object being to displace from the bottle all gases other than CO. The bottle was tightly stoppered and kept in a refrigerator for several weeks. During this time a deposit slowly formed. Two-ml. quantities of the clear supernatant solution were then transferred to standard glass tubes, and again thoroughly gassed with CO. The tubes were immediately sealed. Measurements made by the N.P.L. on these standard solutions show that they suffered a change equivalent to less than 2% of Hb in the last 4 years. Thus weak solutions of CO-Hb can be prepared that are relatively permanent (Donaldson, Harding, and Wright, 1943).

With the usual form of Haldane-Gowers haemoglobinometer a colour difference of 2% haemoglobin on the Haldane scale is just appreciable. This may be taken to be the limit of the method's "accuracy." The Subcommittee recommends this method for the reasons given above and because it finds that the colour of CO-Hb is easier to match accurately than the colour of any other form of haemoglobin used in routine clinical haemoglobinometry. Moreover, the N.P.L. has computed from spectrophotometric data that a mixture of 90% CO-Hb and 10% met-Hb in weak ammonia is closely matched by a standard of 100% CO-Hb in spite of the difference in tint.

For further information on this method and a statement of the uncertainties in it, see Section I.

C. The Present Supply of Apparatus

Accurate 0.02-ml. pipettes and dilution tubes conforming to the specifications of the British Standards Institution* can now be obtained commercially. The supply of commercial CO-Hb standards is less satisfactory, owing to lack of conformity with the defined colour tolerance and the impermanence. The reasons for these defects are being studied, and it is hoped that means for correcting them may be found. It is therefore recommended that when standard colour tubes are purchased it should always be stipulated that the tubes supplied must have been tested at the National Physical Laboratory and found to be in satisfactory agreement with the colour standard. This will ensure initial conformity with the standard. Tubes should be kept in the dark when not in use, and several tubes, preferably of different ages, should be kept and compared with each other from time to time. Should any noticeable differences in colour develop, the tubes should be submitted to the N.P.L. for re-examination; in any event it is desirable that they should be rechecked after six weeks and rejected if substantial change has occurred. Some workers may find it convenient to prepare their own standards according to the method given in the preceding subsection of this report. Such tubes should also be submitted to the N.P.L. for checking before being put into use.

The saturation of the solution of haemoglobin with carbon monoxide may be carried out with ordinary coal-gas; it is preferable, however, to use pure carbon monoxide, which is available in cylinders or can be easily prepared (Peters and van Slyke, 1932a).

D. Note on the Definition of the 100% Haemoglobin Standard

Many definitions have been made in the past, some related to oxygen capacity measurements by Haldane's or van Slyke's methods, others related to the colours developed by standard dilutions of whole blood. There has been no uniformity in the definitions (see table in Clegg and Macfarlane, 1941), and in the past no insistence on uniformity. As a result the 100% reading of one commercial haemoglobinometer may be equivalent to 80% on a second or 120% on a third. It is hoped that the standard defined in the B.S.I.'s specification for Haldane-Gowers haemoglobinometers may lead to uniformity, which is essential if haematological results are to be compared. It is emphasized that the standard now proposed is only an *interim* standard. In the opinion of the Subcommittee a satisfactory 100% standard must be related to total haemoglobin in normal human blood. (See Section I.)

E. Method of Relating Other Standards to the Defined Interim Colour Standard

It is proposed for the present to take the colour standard defined for the Haldane-Gowers haemoglobinometer as an interim basis of standardization of other apparatus and methods. Thus the standard of any other method may be fairly closely related to this standard by comparing it with a calibrated form of the Haldane-Gowers haemoglobinometer specified above. Failing this, O_2 or CO capacities of *normal* bloods may be used as a rough basis of standardization.

F. Recommendation of the Sahli Method where CO Gas is not Available: Criticisms of the Method

Where CO gas is unobtainable the Subcommittee considers that some form of the acid haematin method must be used. Where possible it should be carefully standardized as suggested above and used always in the same way. The colour of acid haematin is known to develop over many hours. Newcomer (1919) has published a simple equation relating the amount of colour developed to the time the blood has been diluted with N/10 HCl. The members of the Subcommittee find the colour of acid haematin difficult to match and the colour wedges and artificial standards supplied with some forms of Sahli instrument often unsatisfactory. The most satisfactory form of artificial standard is thought to be a piece of Newcomer's glass. It has been claimed that substances in whole blood other than haemoglobin can contribute to the colour developed by N/10 HCl from whole blood (Wu, 1922). The B.S.I. Committee which standardized the Haldane-Gowers haemoglobinometer proposes to standardize this instrument also.

III. THE USE OF THE HAEMATOCRIT

The haematocrit is used for two purposes: (1) to determine the relative proportion of cells (red and white) to plasma in a given sample of blood; (2) to determine the total volume of red cells in a given sample of blood so that an estimation may be made, knowing the total red cell count, of the mean corpuscular volume of the red cells in the sample.

---

* B.S. 797–1938 one-mark capillary pipettes. B.S. 1079–1942 haemoglobinometers (Haldane type).

Anticoagulant.—A mixture of ammonium and potassium oxalates causes no shrinkage of the red cells, and must be used if heparin is not available (Wintrobe and Landsberg, 1935). A 2% solution containing 4 parts of potassium oxalate and 6 parts of ammonium oxalate is made up: 0.5 ml. of the solution is added to a series of test-tubes; the tubes are then dried in the oven, and can be stored ready for use.

Blood.—5 ml. of blood taken from a vein with a dry syringe, and without compression, is added to a test-tube containing the dried oxalate and immediately mixed by inversion to ensure solution.

Haematocrit Tube.—The Wintrobe tube is 11 cm. long, with 2.5 mm. bore, and is graduated with a centimetre and millimetre scale 10 cm. in length. The closed end of the tube has a flat bottom. The tube is filled with blood to the 10-cm. mark by means of a capillary pipette. The Wintrobe tube is then centrifuged for half an hour at 3,000 revolutions a minute if the usual clinical centrifuge available in this country is used. The degree of packing is controlled by the centrifugal force, which is dependent upon the velocity and the radius. The majority of clinical centrifuges in this country do not have a speed greater than 3,000 revolutions a minute, and most have a radius of 4.5 in. It is wise, where possible, to check the speed with a revolution counter. Experiment has shown that no further packing occurs if the time of swinging in such a standard centrifuge is increased beyond half an hour. Admittedly, a greater degree of packing occurs if a more powerful centrifuge is employed, but it may result in some deformation of the red cells. A centrifuge that is used for the first time should always be tested to determine that no further packing occurs if the tubes are swung for longer than half an hour. All determinations should be made in duplicate.

1. To determine the volume of packed cells, both red and white, the upper level of the whole cell column is read. It has been shown (Gregerson and Schiro, 1938) that after centrifuging normal blood approximately 4% of plasma still remains among the packed red cells, which means that of the packed-cell volume about 5% is plasma. This observation was, however, made only upon normal blood. It does not appear justifiable to apply such a correction automatically to all blood samples until further data are available. It is therefore suggested that at present no correction in the volume of packed cells be made to allow for retained plasma.

2. To estimate the total volume of red cells, in order to determine the mean corpuscular volume, the lower level of the white cell layer is read. Again for reasons given above, it is probably wiser at present to ignore the plasma retained in the packed cells. If the correction were introduced it would alter all values at present accepted for the normal mean corpuscular volume.

SUMMARY OF THE RECOMMENDATIONS OF THE SUBCOMMITTEE

The Subcommittee is unable to recommend any colorimetric or photometric method for accurate haemoglobin estimation. It finds that there is need for an accurate colorimetric or photometric method that measures total haemoglobin. Iron estimations on washed red cells are recommended as the best available check on total haemoglobin estimation.

Venous blood drawn without stasis is preferred for haemoglobin and haematocrit estimations.

The form of Haldane-Gowers haemoglobinometer recently standardized by the British Standards Institution (B.S. No. 1079–1942) is recommended for clinical haemoglobinometry. All colour standards, whether obtained commercially or specially prepared (see II B and C), should be checked by the N.P.L. Care should be taken to discard any standards that fade or show alteration of tint.

The standard colour defined by the N.P.L. in B.S. No. 1079–1942 is recommended as an *interim* basis of standardization. The Subcommittee finds none of the proposed 100% standards acceptable. It considers that the most satisfactory basis of standardization would be a knowledge of the total haemoglobin content of the bloods of normal men.

Where CO gas is unobtainable the Sahli haemoglobinometer must be used. It should be standardized as suggested.

Red cell volume estimations should be made in Wintrobe's haematocrit tubes spun at 3,000 r.p.m., in the Hearson's centrifuges available in this country, till no further packing occurs. The lower level of the white cell layer is read. As anticoagulant, heparin or a mixture of ammonium and potassium oxalates is used.

CAESAREAN SECTION IN DYSTOCIA

BY

L. G. HIGGINS, F.R.C.S.

The object of this paper is to suggest that the operation of Caesarean section involves less risk than difficult vaginal delivery, and that the indications for abdominal delivery may be considerably extended with advantage to mother and child.

Personal Series

My personal experience is derived from the series of 220 cases briefly analysed below. These include all operations performed since 1931. Before that date records are incomplete, and early cases cannot be included except to remark that there has been no maternal death among them. The later cases fall into two groups, as follows:

GROUP 1—*157 Elective Operations; 4 Notifiable Pyrexia* (2.5%); *Foetal Mortality 5%; No Maternal Mortality*

Indication	Cases	Maternal Morbidity	Infant Mortality
Placenta praevia ..	20	0	2
Grave toxaemia	12	1 Pleurisy and bronchitis	3
Breech ..	21	1 Pyelitis on 12th day	0
Disproportion ..	88	1 Pyelitis on 9th day	1 prem. (error of date) 1 anencephalic
Repeat C.S. ..	16	1 uterine sepsis on 16th day (haem. strep. present)	1 died in 24 hours

A patient is classed as morbid if the temperature rises to 100.4° F. on two occasions in one day of the puerperium.

In all these cases the operation was performed before the onset of labour or when pains had been present for less than six hours. In a large number of such patients the lower uterine segment is imperfectly developed, and in a majority of these cases a vertical "low classic" incision was used, which is truly cervico-isthmial. As a rule the incision just encroaches upon the isthmus, and up to one inch of active muscle is divided. The scar is almost entirely in inactive muscle, well away from the bowels and omentum, and in my experience it heals cleanly without the formation of adhesions.

GROUP 2.—*63 Operations Late in Labour; 8 Notifiable Pyrexia (13%); Foetal Mortality 4.7%; No Maternal Mortality*

Maternal Morbidity	Infant Deaths
Not morbid, 55	2 (failed forceps)
Morbid, 8 (3 chest, 5 genital infections)	1 premature

All the pyrexial cases settled quickly with sulphonamides, and in no case was a positive blood culture demonstrated.

This group may be analysed slightly differently, as follows:

48 failed trial of labour: 3 pyrexial, no foetal death.
15 emergency cases: 5 pyrexial and 2 slightly morbid but not notifiable; 3 babies died.

Nearly all these were cases of disproportion without other disability. In all instances labour had been in progress for longer than six hours. In such cases the lower uterine segment is well developed, and a transverse retroperitoneal incision can be and was employed.

In order to assess the value of Caesarean section it is necessary to estimate the risk to mother and baby. Crude maternal mortality figures are of little value. Many authors have pointed out that the mother is often suffering from some grave complication, by which the outlook is already prejudiced. It is therefore equally meaningless and misleading to quote any mortality rate for "Caesarean section" without the most careful analysis. In a healthy mother the risk is affected chiefly by the operative technique and by the influence of labour. These factors may be considered separately.

Operative Technique

This is of the utmost importance. There is now a great body of statistics which go to prove that the lower uterine segment operation is relatively free from some of the most serious risks associated with the earlier high "classic" incision. The following examples may be quoted:

	Type of Section	No. of Cases	Maternal Mortality
Matthews and Acken (1939) ..	Classic	743	3·9%
	Lower	264	1·9%
Barrett (1939)	Classic	235	4·6%
	Lower	620	2·1%

The former authors report no deaths from sepsis following their 264 "low-flap" operations at the Methodist Hospital, Brooklyn, although many patients were potentially infected. The remarkable control over sepsis achieved by the low cervical technique is now well known. In spite of the fact that this method is usually employed after several hours of labour, with possibility of infection, the incidence of subsequent uterine rupture is greatly diminished, and post-operative obstruction is probably less common. Matthews and Acken concluded that "in the low-flap operations the fatal cases were attributable to the operator." The advantages of this method were stressed by Munro Kerr and Eardley Holland in 1921, and since then many analyses of series of cases have been reported from continental Europe and from America. Among recent authors who have investigated this point may be mentioned Arnot (1936); Quigley (1940); Phaneuf (various articles); King (1940); Feiner (1936); Campbell (1938); and DeLee (various articles). In all these articles the superiority of the low cervical approach is emphasized, and there is now an overwhelming mass of evidence in favour of a low operation. In the following remarks the high classic operation is not considered further, and the low cervical incision is always implied unless the opposite is expressly stated.

The conclusion is that it is no longer possible to justify the general use of the high classic incision, and statistics based upon this operation do not represent the best results obtainable.

Elective Operations

In cases of dystocia the outlook after Caesarean section is profoundly influenced by the onset of labour. It is convenient to consider, first, elective operations upon healthy mothers, performed before the onset of contractions or very early in labour; and, secondly, those cases in which the operation is performed after many hours of labour, when signs of obstruction are more or less well marked.

In practice the coexistence of a healthy baby and a healthy mother who requires Caesarean section occurs principally in those cases showing such marked disproportion that trial of labour is not considered worth while. Cases also come into this group in which the presence of a breech presentation is the main indication. In patients who have had previous Caesarean section the risks may be somewhat increased by the presence of adhesions, but in such secondary elective sections there should be no risk of previous infection, so I have included these cases in the series below, to show the minimal maternal mortality rate under favourable conditions.

	Total Cases	Maternal Deaths	Cause of Death
Individual series:			
Evers (1934)	27	0	
Bailey (1934)	65	0	
Marshall (1939)	101	0	
Higgins (now reported)	125	0	
Hospital series:			
Glasgow Maternity Hospital, 1934–40	279	1	Shock following spinal anaesthetic
Queen Charlotte's Hospital, 1934–9	48	0	
Matthews and Acken (1939) ..	77	0	
St. Mary's, Manchester, 1934–8 ..	105	1	Second operation. Haemorrhage from adhesion
Croydon, 1937–8	41	1	Pulmonary embolus
	868	3	

The only cases included in this table are those in which the operation was performed before the onset of labour or after not more than six hours of labour. It is unfortunate that the total number of cases is so small, but few series are sufficiently well analysed to be included. On the results given, the maternal mortality rate is just over 1 in 300. In each fatal case the cause of death bears little relation to the type of operation. In my opinion Schumann (1939) was justified in concluding that "the elective operation carries with it a fairly negligible risk." He suggests that the maternal death rate in elective cases should be comparable to that of interval appendicectomy. The evidence I have been able to collect and my own experience both support this view.

The conclusion reached is that Caesarean section at the time of election is associated with a much lower maternal death rate than is usually supposed. Probably the risk should not be greater than that associated with any simple laparotomy.

Potentially Infected Cases

The effect of labour upon the incidence of sepsis has been investigated by many authors. Although some confusing results are reported there seems to be little doubt that the maternal morbidity rate begins to rise when labour has been several hours in progress. In this respect the bacteriological investigations reported by Harris and Brown (1927) are most interesting. These authors made cultures of the freshly opened uterus in a series of 50 sections. Their results suggest that in most cases the uterus is no longer sterile after six hours of labour, and that infection is not prevented by intact membranes. The duration of labour pains seems to be of greater importance than the condition of the membranes, and several authors have referred to this. The difference in outlook before and after the onset of labour is well revealed by the figures of Marshall and of my own series analysed below:

Clean Cases. (In Labour for Less than 6 Hours)

	No.	Morbidity	Infant Mortality
Marshall	101	14%	2·0% (2 cases)
Higgins	125	1·8%	2·4% (3 cases; 1 anencephalic)

Doubtful and Contaminated Cases. (In Labour Longer than 6 Hours)

	No.	Failed Forceps	Inductions	Over 40 hrs. in Labour	Maternal Morbidity	Infant Mortality
Marshall ..	70	5	15	18	30%	4·2%
Higgins ..	63	4	7	19	13%	5·0%

Cases with minor infections—offensive lochia, etc.—are not included. There was no maternal death in either series.

These figures, and the many similar series now published, show clearly the rise in the maternal morbidity rate and in the infant death rate that is associated with prolonged labour. In practice, with reasonable care, quite extended labour can be allowed, and I have dealt with cases in which pains had been present and the membranes ruptured up to 5 days. The danger of Caesarean section under these conditions is often exaggerated. On the other hand, when the patient is exhausted, when the vagina is dry and the uterus irritable, and when the position is prejudiced by repeated vaginal examinations, attempted forceps delivery, and vaginal lacerations, a stormy puerperium is likely. Even in such cases delivery can often be completed by section with less trauma than by any other method, and the scope of the operation is not always realized. In an early paper Green-Armytage (1931) has drawn attention to the value of the lower-segment section in place of difficult destructive operations.

The conclusion here is that, when labour becomes obstructed, Caesarean section may be employed as a rescue operation with brilliant success. Nevertheless every effort must be made to prevent a clean case drifting into the potentially infected category by not deferring intervention too long.

Forceps Delivery

In many doubtful cases the attendant will have to decide between the alternative of delivery by forceps or by Caesarean section. In moderate dystocia the conditions under which forceps delivery is thought to be indicated vary rather widely in different schools, as does also the individual outlook. The following tables, compiled from the published records of large maternity hospitals, may be taken to represent the average risk to mother and child of delivery in this manner under good conditions.

Maternal Mortality (Forceps' Delivery), 1931–9

Hospital	Booked Cases		Emergency Cases	
	Total	Deaths	Total	Deaths
A	674	10 (1·5%)	559	22 (3·9%)
B	968	5* (0·5%)	182	4 (2·2%)

* This figure does not include 3 booked cases submitted to craniotomy, in two of which forceps were tried; in one of these the mother died.

It appears that the average maternal mortality rate may be taken as about 1%. Since the mortality associated with low forceps is very small, most of the fatal cases must occur after the relatively uncommon and more difficult operations of high forceps and mid-forceps, in which, therefore, the mortality must be high.

Persistent Occipito-posterior Positions (Forceps Delivery), 1931–40

Hospital	Total Cases	Maternal Deaths	Foetal Deaths
A	177	3 (1·7%)	22 (12·4%)
B	325	2 (0·6%)	47 (14·5%)
C	375	9 (2·4%)	72 (19·2%)

This table is compiled from "booked" cases only, and emergency admissions are not included. The figures serve to show the risks of the more difficult forceps operations. Delivery by forceps may be possible, but unless the foetal head descends below the level of the ischial spines there will be a high maternal and foetal mortality rate. This point has been emphasized by Dodek (1931); and if the foetal head is in an unfavourable position vaginal delivery is a serious undertaking. The average maternal death rate of over 1% for difficult forceps deliveries does not compare at all favourably with the "operative maternal death rate" of about 0.4% for Caesarean section, which represents an alternative method of delivery for this type of case. The high foetal mortality rate after difficult forceps delivery is very striking.

Infant Mortality (Forceps Delivery), Booked Cases only, 1931–9

Hospital	Total Forceps Deliveries	Associated Infant Deaths
A	674	89 (13·2%)
B	968	133 (13·7%)

In *emergency* cases with obstructed labour the foetal mortality rate is very high. In hospital A, among 559 such cases delivered by forceps, the foetal mortality was 145 (26%).

These results cannot be considered satisfactory. It must be remembered that Caesarean section was introduced to save the child, and the operation should be considered in all cases where delivery by the vagina is likely to be hazardous. If this is kept in mind the mother will benefit, as it is scarcely possible to damage the baby seriously without causing injury to the mother at the same time.

The Elderly Primipara and Forceps Delivery

These patients constitute a special category of dystocia for which forceps are often required. In such cases vaginal delivery is an anxious procedure, and the risks for mother and child are certainly increased. Nixon (1931) has shown the high incidence of breech and persistent occipito-posterior positions after the age of 40, and in his series he found the incidence of forceps deliveries to be at least twice as common as in younger women. In another series, analysed by Lossel and quoted by Munro Kerr (1937), the forceps rate rose to 33%. The influence of these conditions upon the infant mortality rate has been carefully studied by the latter author, who gives the following table, with 185 patients in each group.

	Age 20–30	Age 30–35	Age over 40
Forceps rate	4·3%	26·0%	33·5%
Foetal mortality	2·7%	9·5%	13·0%

In the presence of apparent disproportion a trial of labour becomes less and less likely to end successfully as the age increases after 30. This procedure is not really suitable for elderly patients, and most obstetricians would agree that elective Caesarean section should be employed with much greater freedom than in the case of younger women. Attention must be focused not upon the occasional patient who delivers herself with ease but rather upon the greater number in whom labour will be unexpectedly slow and difficult. Unless the presentation is really favourable, few would encourage the middle-aged primipara to attempt vaginal delivery. An occasional unnecessary section does little harm, but one too few will mean a disaster.

The conclusion is that in the presence of dystocia, when vaginal delivery is possible but difficult, the use of forceps is associated with definite risk to the mother, and the outlook for the child is bad. Delivery by Caesarean section should be more often used in these cases.

Discussion

The figures given above for forceps delivery go to prove that even slight disproportion has a very serious effect upon the outlook for both mother and child. In the presence of dystocia, when labour is often prolonged, the use of forceps carries an obvious practical and theoretical drawback, because delivery cannot be completed until the cervix is fully dilated. When the head ceases to advance, this may never occur, and in other cases the first stage may be prolonged and the mother may develop fatigue before dilatation is complete. With fatigue will come increased possibility of infection and all the dangers of retained placenta and post-partum haemorrhage, while the baby may not survive. It cannot be disputed that a healthy woman is sometimes allowed to drift into a dangerous condition in this way while actually under the observation of her medical attendant. All such cases demand immediate delivery, without aggravation of the tendency to shock which is so often present. Under such conditions it is difficult to see the object of waiting until vaginal delivery by forceps is possible. Even if the infant is born alive the dystocia must be overcome by stretching or tearing of the maternal soft parts. The birth of a second child may be easier, but the mother has paid the price in her damaged pelvic floor. It is better to realize that when labour departs from the normal pattern the process becomes pathological, and delivery is not necessarily normal because it is vaginal. Indeed, it may be easier to repair a cut in the abdominal wall than a laceration of the pelvic floor. In all such cases it seems to me that the trauma to the mother is less and the outlook for the child is much improved if delivery is accomplished by Caesarean section.

Late Maternal Morbidity

Although the immediate maternal morbidity associated with forceps delivery is appreciable, it is probable that the late sequels are of even greater social importance. A difficult vaginal delivery produces great trauma, and it is easy to damage the mother's pelvic floor to a degree which can never be repaired. I have painful recollections of cases, thought at the time to be quite successful, in which difficult vaginal delivery was effected. Three months later the mother was still tired, listless, and drooping, with backache, leucorrhoea, and a dribbling bladder, spoilt as a wife and as a mother, and unable to enjoy the child fortunately born alive. It is scarcely possible to assess the frequency of sequels of this kind, but undoubtedly they are common. The late Prof. Blair Bell (1931) estimated that each year 60,000 women are more or less seriously crippled by childbirth, and a large proportion of the graver damage must occur at difficult forceps extraction. Such cases show a strong contrast with those delivered by Caesarean section, who are remarkably free from late morbidity. Indeed, it is encouraging to see how quickly the latter regain their original figure and carriage.

Rupture of the uterine scar at a subsequent pregnancy or labour may be classed with late maternal morbidity. In a recent textbook (Browne, 1939) the incidence of this accident is estimated at 4% in the case of high classic operations. There is little doubt that this figure is based upon old statistics, and at the present day the accident appears to be less frequent. As a sequel to lower-segment operations, subsequent rupture of the scar is certainly most exceptional. Discussing this point, Marshall (1939) stated that 50 cases had been recorded at that time, of which only 5 followed the transverse incision. It seems probable that, with modern technique, the possibility of rupture of the scar may be almost ignored. Marshall remarked that no case had occurred in the practice of the Liverpool Maternity Hospital or in DeLee's clinic at Chicago, and I have been unable to discover a record of such a case in a long series of clinical reports recently examined.

The Sterile Labour

Consideration of the infant morbidity will introduce the important psychological effects of the fruitless labour. The mental shock of losing an infant, especially if it is the first one, may remain throughout life. It is often a factor in causing dread of childbirth, with nervous tension and thwarted ambition, drifting steadily towards a childless and hypochondriac middle-age. It is impossible to gauge the incidence of this unfortunate sequel, but I am sure that it is far more common than many suppose. In my opinion it is of the greatest importance, if only for psychological reasons, that the first baby should be born strong and healthy. The prospective patient attends the maternity hospital in order to have a healthy infant, and she expects difficulties to be overcome, so that she will survive her confinement with full vigour for her maternal responsibilities. The loss of a healthy baby in a healthy mother must mean a serious breakdown in obstetrical care.

The presence of dystocia, therefore, should no longer be accepted as a legitimate reason for a raised infant mortality rate.

Trial of Labour and Obstruction

In normal patients a spontaneous delivery under good conditions is associated with a minimal maternal mortality rate of considerably less than 1 in 1,000, and it is probable that really low forceps, with the foetal head below the level of the ischial spines, may almost be classed with this group. Before the onset of labour there can be no absolute distinction between normal and abnormal cases, and in spite of the assistance given by radiography the available methods for the detection of dystocia are notoriously unreliable. In a series of 6,500 deliveries analysed by Alice Maxwell (1927) dystocia occurred in less than half the cases with recognizable pelvic contraction, while more than half the total cases of dystocia appeared when no pelvic abnormality could be detected. A small experience will show that in every woman the first labour is always a trial, and it is surprising how often difficulties arise when they are not expected. On the other hand, it is well known that many young patients with slight disproportion will achieve an easy spontaneous delivery. In such cases the maternal risks are not increased and the infant mortality rate shows only a slight rise, an extra risk which must be taken. In an average series showing clinical disproportion, it may be supposed that a spontaneous delivery will occur in about half the patients. Bailey and Williamson (1927) analysed such a series of 676 cases with great care, and recorded a spontaneous delivery in 66%. No method of operative delivery could give results comparable with those obtained by normal labour, and it is therefore of the greatest importance to refrain from interfering unless this is really necessary for the safety of the mother or child. The object of a trial is to encourage a normal spontaneous or low forceps delivery, in which cases the results are good. A difficult vaginal delivery is not worth while, and the results for both mother and baby are inferior to those of Caesarean section. Excluding purely technical faults, a damaged baby following a forceps extraction is usually evidence of an error of judgment in choosing vaginal delivery. The dangers of unexpected dystocia may be illustrated by the following series of 16 cases of disproportion taken from a clinical report for 1938 of a well-known teaching hospital. All these occurred in booked cases which showed no evidence of pelvic contraction.

8 cases of spontaneous delivery, including one case with P.P.H. which required manual removal of the placenta and two blood transfusions.
1 case of forceps delivery.
1 case of delivery by forceps after perforation.
3 cases of craniotomy.
3 cases of Caesarean section after many hours of labour. One of these went septic. One baby was stillborn and another died.

Altogether 6 babies were stillborn or died, while of the mothers 2 developed puerperal pyrexia and 3 puerperal sepsis. Clearly the results would have been better if every woman in this series had had a Caesarean section before the onset of labour.

In managing a test of labour it is important to avoid allowing the condition of the mother or baby to deteriorate before making the decision to perform section. The investigations of Harris and Brown, referred to above, suggest that labour for six hours is relatively harmless, and, in practice, awaiting the onset of labour will help to exclude the possibility of premature delivery. At the end of this time it is usually possible to decide whether a normal vaginal delivery can be expected. In longer trials which end in Caesarean section the morbidity rate will tend to rise. Arnot (1936) found the test of labour the biggest causative factor in producing serious pyrexia, and there is little doubt that there is a strong temptation to allow the test to continue too long. In certain cases it is only too easy to allow the patient's outlook to become prejudiced. This must be avoided, although the introduction of the sulphonamides has done so much to improve the treatment of pyrexia. It is an unfortunate drawback to delivery by section that the operation is safest before the onset of contractions or very early in labour, at a time in some cases when the necessity for section cannot be foretold with certainty. It would be of very doubtful benefit to the patient to deal with every potential difficulty by Caesarean section, and in order to avoid this the attendant must feel a challenge implied to achieve normal delivery in every doubtful case. In proportion as the operation becomes safer, the tendency to employ it more freely must increase. Indications may be extended in scope, but they remain fundamentally the same, including only those cases in which delivery by any other method would involve increased danger to the mother or child. At the same time, the results of elective section are now so good that only the smallest margin of error can be allowed in trial of labour, and no bad effects for mother or baby must occur or the whole object of the procedure will be frustrated.

Summary and Conclusions

A personal series of 220 cases of Caesarean section by the lower-segment technique is reported and briefly analysed. A consideration of this and other reported series suggests that the maternal mortality rate in this operation should not exceed 1 in 300.

The consequences of forceps delivery are considered and the unsatisfactory results for mother and baby are pointed out. In view of the encouraging results of Caesarean section, the legitimate indications for forceps delivery require careful review.

The outlook towards Caesarean section should be completely readjusted, and the operation must be used much more freely in serious dystocia to avoid the maternal and foetal morbidity often reported.

SOCIAL ASPECTS OF ALLERGY

BY

E. M. FRAENKEL, M.D.
Southern Group Laboratory, L.C.C. Park Hospital, London, S.E.13

Only very recently has proper attention been paid to the environmental factors, in occupations and in home surroundings, which are concerned in the onset and course of disease. Apart from the so-called occupational diseases, the environmental factor is more or less in the foreground in a number of conditions—e.g., certain groups of malignant growth or infections like pulmonary tuberculosis—and it is particularly evident in the group of conditions now classified as allergic diseases. My own observations are based on the examination of more than 1,000 cases of bronchial asthma and other allergic complaints during the last 14 years. Of these, 522 are asthmatics observed in Germany from 1928 to 1932, 365 of them employees seen under the German national insurance scheme; and 489 were cases observed in England since 1934. Of the latter 268 were hospital patients—103 seen at the Westminster Hospital up to 1938, and 165 examined since 1938 at various (17) L.C.C. hospitals.*

Asthma and Other Allergic Conditions in Occupations and Military Service

Most frequent, and of the greatest clinical and social importance, are the allergic complaints of the respiratory tract (bronchial asthma, rhinitis including certain forms of sinusitis, and polypi) and those of the skin (eczema, dermatitis, urticaria, and Quincke's oedema). Rarer and perhaps less well studied are alimentary diseases such as spastic colitis and other spastic conditions of the digestive tract or bile ducts, migraine, and a number of others. In the Services serum sickness and allergy to prophylactic or therapeutic inoculations have to be considered as possible complications.

In all allergic conditions intrinsic (often constitutional) and extrinsic (mostly allergic) factors play their part. Their role is of varying importance not only in each of the conditions and in every patient but also because they change in the same patient at various periods of life.

As the *intrinsic*, predisposing, constitutional factor—endocrine, metabolic, or anatomical—is often inherited, allergic complaints run in families in more than 50% of the cases, according to my observations, and frequently follow the patient during a long period of his life. He may suffer either from one or from more than one of these conditions at varying periods. Allergy is itself a normal body reaction and defence mechanism like immunity, and actually represents the state short of and antecedent to immunity in which increased sensitivity precedes the greater resistance provided by the immunity. Only when this sensitivity remains and becomes a feature of definite clinical illness are we entitled to speak of the condition as "allergic disease."

The *extrinsic* factors—the allergic irritants—are incorporated (1) by inhalation (aerogenous), (2) by ingestion (enterogenous), (3) by touch through the skin (dermatogenous), or (4) by parenteral inoculation. Intrinsic allergic irritation may be caused by resorption of bacterial proteins from focal infections, bronchiectasis, or tuberculous infections. On the other hand, there are definite extrinsic irritations which do not act as allergens but as auxiliary predisposing factors—e.g., SO_2 gases in the air in certain industrial areas. It is still doubtful whether ursol acts as an allergen or in the same way as the SO_2, preparing the mucous membranes for an irritability to allergens.

Allergens are mostly of protein nature, but definite chemical compounds are known to become allergens through the formation of protein compounds in the body, as in the case of group-specific chemical antigens (Landsteiner). The allergen does not always produce clinical signs at the place of entry (reflex or trigger area)—e.g., it may be ingested and cause urticaria in the skin or asthma in the respiratory tract. The allergy often starts with a sensitivity to *one* allergen or to a few allergens that spreads to others if not treated. A patient may have a seasonal hay-fever at first and then become sensitive to moulds or dust: the monovalent allergy becomes polyvalent.

Sutherland (1942a, 1942b) recently stated that the "extrinsic" cases of asthma are suitable for military service and can be easily cured by desensitization. These were obviously cases in the monovalent phase of the condition. The "intrinsic" cases are in his opinion not fit for military service. These are the cases in which the threshold of parasympathetic irritability has been lowered by a longer duration of the allergic condition or in which constitutional factors or focal infections are in the foreground. I (Fraenkel, 1934a, 1934b) have reported that, contrary to an old belief, asthma and tuberculosis of the lungs do not exclude each other: a form of active tuberculosis appeared "masked as asthma" in 4% of my asthma cases. In 16% of my asthma cases an old or productive pulmonary lesion was found.

I have stated previously (Fraenkel, 1937a, 1940) that *prognosis* in asthma depends on the following factors: (1) whether organic changes complicate the condition as a contributing cause of or as a sequel to the asthma—e.g., bronchiectasis, chest deformity, pulmonary tuberculosis or other infections, emphysema, or heart failure; (2) whether the family or personal history reveals a preponderance of constitutional factors; and (3) whether the allergen is easily avoidable or can be immunized against by a course of desensitization. *Mutatis mutandis*, this applies to prognosis in other allergic conditions. House allergens are the most common, but in England the damp climate is responsible for sensitivity to moulds in more than 50% of asthmatics (Fraenkel, 1938, 1939), and, by infection of the respiratory tract, for frequent bacterial sensitivity to the germs of the common cold. In many instances I have isolated the same types of mould from the patient's house allergens and from his sputum and used them for skin tests and desensitization. The moulds most often found positive in skin tests were sporotrichum, cladosporium, penicillium, aspergillus, mucor, and monilia types, and they are probably responsible for the intolerance to certain rooms, houses, or localities experienced by many asthmatics.

Clinical Investigation

This conception makes it necessary in every case to take a very careful history, which comprises a special inquiry into family and personal allergy, and also into occupational and personal aspects of the patient's life apart from the ordinary medical history. Investigation into all signs of parasympathetic irritability, local and blood eosinophilia (polyps, nasal secretion, sputum, or mucus in stools), and a full clinical examination including radiographs of chest, nasal sinus, and antrum, are preliminaries to the specific examination for allergy by exposure and elimination tests. These include scratch, intracutaneous, or mucous membrane tests for the allergens as suggested by the history, or the use of allergen-free rooms, a diet, or filter apparatus (allergen-free bags or masks) (Fraenkel, 1937b, 1937c). These methods can be employed for diagnostic, prophylactic, and therapeutic purposes.

---

* I wish to express my thanks to the London County Council health authorities, to the staffs of the hospitals, and especially to Dr. J. McCartney, Director of the Research and Pathological Services, Southern Group Laboratory; also to Mr. Morley and Mr. Hackett for the invaluable support they gave me in my investigations.

Certification of Cases for Fitness in Occupations or Services

It is evident that cases without organic complications and without a family or personal history of other allergic complaints are the most readily adjusted to industry, particularly those in which one or only a few easily avoidable allergic factors can be established, and eliminated—e.g., urticaria after strawberries or lobster, or rhinitis caused by a fur coat or collar. Next come those in which definite allergy is established by history and specific tests and is improved or "cured" by desensitization—e.g., pollen rhinitis or asthma. Where the allergen is difficult to avoid, as in common food (egg, milk, wheat), climatic or house allergens, moulds, etc., this is the method of choice. These subjects are probably fit for most occupations and for the Services. On the other hand a man with fur sensitivity should not work as a furrier, or a man with sensitivity to wool in the tailoring trade. A man with pollen allergy may be well or be cured in the Navy and yet be unfit for the Army. Patients sensitive to horse-hair or horse dandruff would be unfit for the old cavalry but not for the mechanized tank regiment. Organic complications such as bronchiectasis or heart failure in asthma or the asthma type of tuberculosis make the patients unfit for all but light occupations. Pollen allergy or the mould allergy in tomato-growers due to *Cladosporium fulvum* Coke may be a contraindication to gardening. Sensitivity to certain drugs like salicylates or ipecacuanha contraindicates a job as a chemist. A person who has shown signs of allergy should be tested before being taken into trades in which the danger of allergic irritation exists. This can be done by skin-scratch or intracutaneous tests in such instances as fur sensitivity or allergy to wool in the tailoring trade, or by Jadassohn's patch test in cases of skin sensitivity to chemical irritants occurring in many industries Allergy to grain dust, to feathers, or to horse dandruff may be a contraindication to employment on farms, and allergy to flour for millers and bakers. The same person may remain well and fit in another occupation.

These *occupational factors in allergy* are definitely of less influence than house allergens, house dust, feathers, or mattress contents, or moulds cultured from them, because of our closer and longer contact with the latter; they, however, are by no means unimportant. Ancona and Frugoni have reported a type of asthma observed in all farmers, millers, or bakers who came into contact with grain infested by a tinea-producing species of an acarus type—*Pediculoides ventricosus*. The allergen worked like an obligate contaminating germ in 100% of those exposed, and the asthma cases would certainly be "accidents" of occupation in the proper sense of the term. The same applies, in my opinion, to a great number of allergic cases in which the occupational exposure is responsible for the onset of an allergic complaint as proved by the history and by specific tests. I have mentioned such instances in millers, bakers, and farmers who are sensitive to flour, in farriers, farmers, and horsemen who are allergic to horse-hair or horse dandruff, and in gardeners or fruiterers with allergy to the cladosporium mould on decaying tomato plants. There are, further, furriers or tailors or carpet-makers with allergy to fur or wool or to the dyestuff ursol used in the trade. Lead asthma is well known, as is the asthma due to salicylates or ipecacuanha occurring in chemists. There are also skin irritations, eczema, and dermatitis due to certain types of wood.

The degree of sensitivity of the patient is often decisive. Mayer reported a case of eczema in a workman who got it by contact with a friend who had worked with phenylhydrazine; and another case in which a man became sensitive to ursol when, on the way to his work, he passed by a workshop where this was used. Sometimes a solvent is responsible for a substance becoming allergenic that was innocuous in a different medium.

Compensation Claims

Under the law compensation is paid to workmen only when the occupation and the substance come under the Workmen's Compensation Act, and this applies to but a small number of the actual occupational allergic diseases. A workman in a chemical factory may be entitled to compensation in case of lead asthma or toluidine dermatitis. A tailor with asthma due to wool or fur would not obtain compensation, but he might in case of ursol dermatitis or asthma. A chemist would not be entitled to claim for ipecacuanha asthma or asthma due to salicylates, which I have observed to develop into pulmonary tuberculosis in one case under constant medical supervision. Sometimes a small impurity or a change of a manufacturing process is responsible for the allergy. The present law allows compensation claims for ladies who are allergic and get an eczema from a fur coat or collar dyed with ursol, which I think rather unfair to the salesman.

These examples show that both jurisdiction and legislation are not abreast of present-day knowledge of allergic diseases. In many trades, too, protective measures could be improved, thus providing greater safety for the working population and avoiding considerable expense.

Suggested Protective Measures

1. Allergic diseases are of essential social importance owing to their long duration, especially in the most active periods of life, and to their connexion with the environmental factors in home surroundings and in occupations. In many cases they are responsible for recurring inability to work, leading often to invalidity or, as with the complications of bronchial asthma, even to death.

2. Legislation, jurisdiction, and public welfare should be adapted to our present-day knowledge of allergic diseases, and many more centres for diagnosis, prevention, and treatment should be provided, with staffs trained in the clinical and laboratory side of the problem, and with all the necessary equipment, as in the U.S.A.

3. These centres should be available to doctors for the investigation of their private and panel patients, to the military and civil authorities, and to the industrial and health organizations.

4. They should deal with examinations for certificates for fitness in certain occupations or for the Services, with compensation claims, and with cases in which legal expert advice is required.

5. Their investigations must be based on a careful history which takes into account the constitutional and environmental factors, and on an examination which includes *x*-ray findings, eosinophil counts, and the specific methods of elimination and exposure tests, apart from the routine examination.

6. These methods must include skin and mucous membrane tests, elimination by diet or allergen-free rooms or apparatus, etc., and the use of preventive or curative desensitization, besides treatment of dispositional or auxiliary factors.

7. The centres could protect a great number of patients from premature invalidity or even death, and in other cases considerably shorten the periods of actual illness and thus save man- and woman-power and expense. They would also greatly contribute to teaching and research in allergy.

L. Stein and E. Wertheimer (*J. Endocrinol.*, 1941, **2**, 418) state that adrenalectomy causes an intense though transient increase in the rate of loss of hair in rats. Along with this there are secondary symptoms ranging in severity from dandruff to extensive ulcer formations. Similar symptoms were observed in medullectomized rats. It was found that an acid extract of adrenal medulla could inhibit this loss of hair, which could also be brought about by a synthetic *l*-adrenaline

MENINGEAL REACTION IN A CASE OF GLANDULAR FEVER

BY

J. SHAFAR, M.D., M.R.C.P., D.P.H.

AND

J. C. R. WEIR, M.B., Ch.B.

Medical Officers, Mearnskirk E.M.S. Hospital, Renfrewshire

During the last six months numerous examples of a clinical syndrome which is characterized by enlargement of the lymphatic glands have been observed among members of the Senior Service. The groups of glands in the posterior triangles of the neck and in the axillae have been typically involved in a discrete, painless, and only slightly, if at all, tender swelling; the axillary masses attained the size of a small tangerine, whereas the glands in the neck remained relatively small, being palpable as numerous shotty lumps. The usual presenting features were headache of a persistent and severe type, stiffness of the back of the neck, and general malaise. Epistaxis was a not infrequent accompaniment. More recently, abdominal symptoms consisting of nausea, vomiting, and abdominal pain have predominated; the abdominal pain had led to a mistaken diagnosis of subacute appendicitis on several occasions by the medical officer submitting the case, a diagnosis which seemed further supported by the marked tenderness over the right iliac fossa. Distinguishing signs in such instances were the presence of a mass of enlarged glands in both iliac fossae and tenderness in these areas. The other sets of glands involved in the malady were the mediastinal and inguinal groups. The former did not produce any specific symptoms, but were demonstrable by radiography.

The disorder has a benign course, and, apart from perhaps a mild pyrexia in the early stages of the condition, no upset of the temperature or pulse rate occurred. Within one to four weeks the patient was free of symptoms, although the glandular swellings required a much longer period before disappearing. Splenomegaly was rarely encountered. The infectiousness of the disorder was made apparent by the incidence of new cases in the same ward and by its development among a number of the medical and nursing attendants.

Differential counts of the white cells of the blood were carried out, and in practically all a deviation from the normal was demonstrable. The polymorphs totalled some 50%, the remainder being made up of small and large lymphocytes and an average of 10% of monocytes. The Paul-Bunnell reaction was negative with but few exceptions.

The relation of the disorder to glandular fever (infective mononucleosis) requires consideration. The general behaviour of the condition would well fit in with such a diagnosis, but the exceptional exhibition of heterophile antibodies must occasion some doubt. Prof. Paul (1941) draws attention to the discrepancies of this reaction. In his own series of 50 cases he obtained 90% positives, whereas he quotes Erf (1936-7), who found that not more than 40% of cases yielded a positive result. Paul rightly argues that the percentage must be influenced by the diagnostic criteria and by the frequency with which the serological tests are made during the disease. The latter surmise is borne out by the example reported by Himsworth (1940), in which the reaction was negative in the early stages of the illness but subsequently became positive 11 weeks after the onset of symptoms. Further observations are necessary before it can be asserted whether distinct categories can be segregated from infectious mononucleosis on the basis of the presence of agglutinins in the patient's serum to the red blood corpuscles of the sheep, or their absence. What has been convincing, however, is the clear-cut clinical picture and course presented by our cases, which now number almost 200. The similarities to infectious mononucleosis are so many that until further evidence is forthcoming regarding the existence of separate and distinct varieties of "glandular fever" we feel justified in including our cases under this diagnostic title.

Complications have been very few. Jaundice was seen on three occasions. Since it was of an obstructive type, and since catarrhal jaundice had been so prevalent in the wards, the coexistence of these two maladies could not be excluded. A mild bronchitis and nasopharyngitis were not uncommon. A skin rash was seen in 4 instances; but it differed individually in appearance, and in all cases was evanescent.

The case presented here is the sole example of a neurological disorder encountered in the series.

Case Report

The patient, a man aged 28, was admitted to hospital on June 17, 1942, with generalized body pains, malaise, and sore throat of a month's duration. His only significant illness in the past was an attack of pneumonia 11 years ago; he was subject to recurrent attacks of tonsillitis.

Examination showed an unhealthy and congested state of the tonsils and nasopharynx, enlarged discrete and painless lymphatic glands in the neck, axillae, and inguinal regions; and scattered rhonchi in the chest. No clinical evidence of disease was discovered in the other systems. The temperature and pulse rate were normal. There was little alteration in his condition until June 22, when he then complained of severe frontal headache, and in the early hours of the next morning became delirious and restless. Examination revealed rigidity of the neck, photophobia, generalized hyperaesthesia, and a positive Kernig sign. No other objective abnormal signs were found in the central nervous system or in the optic fundi. The temperature had risen to 101° F. and the pulse rate to 100 Chloral and bromide were administered with good effect. In the afternoon of June 23 the above findings were more pronounced and the temperature had risen to 103° F Lumbar puncture was performed, milky fluid being obtained. On analysis this showed a centrifugalized purulent deposit, gross increase in cellular content, and Pandy test + +; there were no organisms in the direct smear or on culture. A differential count of the cells of the C.S.F. showed: polymorphs 87%, large lymphocytes 3%, small lymphocytes 6%, monocytes 1%, endothelial cells 3%. He was placed on sulphapyridine, which was discontinued after four days. On the day after the lumbar puncture a marked improvement in his condition was observed His pulse and temperature were at normal levels and his delirium and incoherence had disappeared; the frontal headache and the nuchal rigidity were, however, still present. A further lumbar puncture was carried out on June 24; the fluid on this occasion was opalescent and contained a slight purulent deposit. The Pandy test was positive, the Wassermann reaction negative, and a large excess of cells were found (polymorphs 70%, large lymphocytes 4%, small lymphocytes 6%, monocytes 11%, endothelial cells 9%); again organisms were not demonstrable.

The patient continued to improve, and three days from the onset of his meningeal reaction his condition was most satisfactory: the nuchal rigidity and headaches were gone and his temperature had remained normal. The C.S.F. at this date showed a fibrinous pellicle, but was otherwise gin-clear; the Pandy test gave a very faint positive reaction, and the cells were few in number and mainly lymphocytic in type. Culture of the fluid failed to grow any organisms. The results of an examination of the C.S.F. on June 27 were: fluid clear, no pellicle on standing, Pandy test ∓, W.R. negative, and but a few cells of the large lymphocytic class. On the 30th C.S.F analysis gave a result identical with that obtained on the 27th. The patient's progress was satisfactory and he was symptom-free—although the lymphatic glands were still palpable, but smaller—until July 1, when he developed a fresh tonsillitis with secondary enlargement of the draining lymph glands in the neck and a pyrexia of 101° F. A throat swab showed diplococci in short chains, while Vincent's or Klebs-Loeffler's organisms were not found. The inflammatory reaction of the throat cleared up in three days. No further developments occurred and, apart from the persisting but steadily diminishing enlargement of the glands, the patient appeared to have made a complete recovery. He was discharged for a period of convalescence, following which tonsillectomy was recommended.

Differential white cell counts of the blood gave the following results:

	June 18	July 27
Polymorphs %	79.1	51
Large lymphocytes %	12.7	28
Small lymphocytes %	0.8	11
Monocytes %	6.8	7
Eosinophils %	0.5	3

A blood count (July 3) showed: red cells 5,200,000, Hb 90% white cells 14,500. The blood W.R. (June 27) was negative. Two Paul-Bunnell reactions (June 19 and July 7) were negative.

A guinea-pig was inoculated with C.S.F. on June 24 and suffered no ill effects; necropsy performed on July 28 showed no evidence of disease.

Discussion

Uncomplicated infectious mononucleosis invariably has a benign outcome, and sequelae of any significance are rare. Nephritis is not an uncommon event in the course of the disorder, but the renal function remains unimpaired and rapid recovery ensues. Haemorrhagic phenomena, pulmonary features, and jaundice are other complications, and attention has recently been attracted to involvement of the nervous system. Bernstein (1940) details the neurological manifestations encountered prior to the date of his monograph. Peripheral cranial nerves are rarely affected, but persistent anosmia and facial palsy have been recorded. Paresis of the extra-ocular muscles (Fledelius, 1935) and photophobia and nystagmus associated with poor articulation (Marshall, 1939) have also been reported. An extraordinary example of glandular fever with a strongly positive Paul-Bunnell reaction, in which a paralysis of the serratus magnus muscle developed during the third week of the illness and which cleared up in about four months, is described by Richardson (1942). The meninges appear to be the commonest site of affection, and Bernstein states that in at least 12 cases of glandular fever the clinical picture of serous meningitis has been found. Often the meningeal features antedate other manifestations of the disease. Nuchal rigidity, positive Kernig and Babinski signs, convulsions, and mental changes have been present in certain of such instances. Bilateral optic neuritis (Gsell, 1937) appeared in one case. The cerebrospinal fluid in the meningeal syndromes accompanying infective mononucleosis usually contains an increased protein and cellular content (chiefly lymphocytic in type), but examples have been reported in which the fluid has been normal in spite of unmistakable clinical signs of meningeal irritation (Huber, 1938). Huber also mentions a case in which the pleocytosis attained a level of 1,000 cells per c.mm. The condition of the spinal fluid in uncomplicated glandular fever is of some interest, but is neither constant nor characteristic. Excess of cells and positive Pandy reactions have been mentioned, but the sugar content and colloidal gold curves remain normal, and the Wassermann reaction is negative even in the presence of a false positive in the blood. Culture of the fluid has proved negative except on four occasions when Listerella were isolated (Schmidt and Nyfeldt, 1938).

A recent communication (Landes, Reich, and Perlow, 1941) deals with a case of infectious mononucleosis the early symptoms of which simulated those of encephalitis. Of particular importance with regard to our own case is the report by Thelander and Shaw (1941). They described 3 cases of neurological complications. The first was that of a meningitic picture in the course of infective mononucleosis; the peculiarity noted here was the fact that the cerebrospinal fluid, which at the onset contained 630 cells per c.mm., at the end of four months continued to demonstrate a pleocytosis consisting of 82 cells per c.mm. The Paul-Bunnell reaction was strongly positive. The two other cases occurred in sisters, one of whom, aged 3½, was suddenly affected by fever, pain in the back of the neck, and a convulsion. No glandular or splenic enlargement appeared during the illness. The C.S.F. contained 40 lymphocytes per c.mm., and the blood showed a white cell count of 17,000 per c.mm., with the polymorphs accounting for 69% of the total. Encephalitis of unknown aetiology was diagnosed. Four days later the other sister, 2½ years of age, became ill with similar symptoms. The cells in the C.S.F. amounted to 70 per c.mm., and were chiefly lymphocytic in type. The total leucocyte count of the blood was 45,700 per c.mm., and a differential count revealed that 81% of these were lymphocytes. Again no enlarged glands or spleen could be found, and the Paul-Bunnell reaction was negative. The authors consider that the findings in the last two cases point either to a diagnosis of infectious mononucleosis or to a hitherto undescribed pathological syndrome, and refer to their large experience with benign lymphocytic meningitis and encephalitis, in neither of which conditions had they seen cases in which the blood picture or the results of serological tests suggested mononucleosis. The third of Thelander and Shaw's cases and the case reported here present many features in common. The large numbers of cases in our series, referred to above, showing similar signs and symptoms and running a similar course, would appear to support our contention that the group, if not glandular fever (as manifested by the demonstration of heterophile antibodies), has a common aetiology and forms a clinical syndrome, of which the present case is unique in the manifestation of a meningeal reaction.

We wish to express our indebtedness to Dr. J. A. Wilson, medical superintendent, who kindly carried out the laboratory investigations, and to Dr. A. M. Scott for his interest and advice.

THE RADIOGRAPHIC POSTERO-MEDIAL BORDER OF THE LUNG

OR THE LINEAR THORACIC PARASPINAL SHADOW

BY

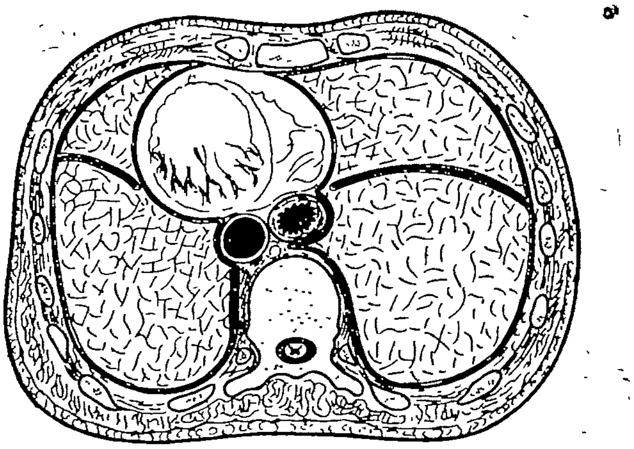
JAMES F. BRAILSFORD, M.D., Ph.D., F.R.C.P.
Radiological Demonstrator in Living Anatomy, University of Birmingham

Under the latter title an editorial in *Radiology*, Aug., 1942, p. 229, draws attention to "a slender line of demarcation which is often seen in antero-posterior or sagittal roentgenograms of the bony thorax and upper abdomen. This line lies on the left side of the lower two-thirds of the thoracic spine and sometimes continues as far down as the plane of the first two lumbar segments. The shadow is frequently an enigma to radiologists and other clinicians viewing such roentgenograms. It is not visible on all films or projections of this portion of the body, but is observed with such frequency that it must be the result of variation in the course and position of a normal structure situated therein." Then follows a discussion in which it is inferred that it is not bony, not due to unilateral spinal ligaments, descending aorta, or inferior vena cava, "but it might be an enlarged and elongated hemiazygos vein." "This editorial is written with the suggestion that this finding be referred to as the left thoracic paraspinal shadow and that its frequency be noted by various radiological observers. In this manner its true incidence may be ascertained and its apparent nature confirmed."

An Important Diagnostic Sign

This radiographic line of demarcation is of great importance in the diagnosis of lesions involving the lower dorsal and upper lumbar spine. It is often seen on the antero-posterior radiographs of the dorso-lumbar area on the left side, but it is seen, though less often, on the right side as well. It extends upwards sometimes to the level of the 4th dorsal vertebra, but only as far as the reflection of the pleura on to the diaphragm, for *it marks the postero-medial border of the lung*. As will be seen from the accompanying sketch of a cross-section of the body at the 9th dorsal level, the postero-medial border of the left lung, which has been more thickly outlined for emphasis, lies in a direct sagittal line for two or more inches. For the whole of this distance it is separated from the vertebral body by the pleura, fascia, and some areolar tissue. On a plane with the anterior surface of the body it is displaced laterally by the descending aorta and more anteriorly by the heart. On the right side the medial border of the lung extends partly over the anterior surface of the vertebral body and is displaced laterally by the oesophagus and the heart. Antero-posterior radiographs of this area will therefore show the postero-medial boundary of the lung as a straight line lateral to the outline of the vertebra, because on the lung side of the boundary the tissue is relatively radiotransparent, whereas on the vertebral side the tissue is much more radio-opaque. The descending aorta, being more opaque than the lung, will also be seen as a linear shadow lateral to the postero-medial border of the lung where it is superimposed over the postero-medial aspect of that organ. On the right side, because of the shelving margin of the postero-medial aspect of the right lung, there is usually no sharp line of demarcation between it and the denser medial structures; consequently the border cannot be seen. It is for the same reason that the more anterior of the medial borders of the lung are not shown.

A glance at the sketch will reveal at once why this line has great diagnostic significance, for it shows the close relation of the medial border of the lung to the lateral surface of the vertebral body. If the latter is crushed its transverse diameter will be increased and the medial border of the lung will be displaced to that extent laterally. If the fracture is associated with a paravertebral haematoma this will show as an added expansion and further lateral displacement of the medial border of the lung. The antero-posterior radiographs show this as a fusiform expansion of the medial opacity, for the postero-medial border of the right lung will be similarly displaced. In a case which came to court the existence of a crush fracture of the vertebral body was disputed until the presence of a paravertebral haematoma was demonstrated to the judge on the radiograph taken immediately after the accident and its absence from radiographs taken a fortnight later. But the commonest demonstration of lateral displacement of the postero-medial border of the lung is due to the paravertebral tuberculous abscess. It is important because it may be detected before any change in the bone has become apparent. The abscess may extend the whole length of the dorsal spine, is usually fusiform in shape, and is sometimes of the width of the heart shadow; indeed, it has occasionally been missed because it was mistaken for the latter. It may show progressive expansion from the time it is first detected. Because from the level of the reflection of the pleura on to the diaphragm there is below no contrast in the densities of the adjacent tissues, the outline of the abscess cannot be traced in the abdomen—i.e., we are dependent upon the lateral displacement of the postero-medial border of the radiotransparent lung for visualization of the abscess. Consequently, though the abscess may have arisen from caries of one of the lumbar vertebrae, if no bone changes are yet recognizable its origin may not be apparent.



Transverse section of body at 9th dorsal level. The thickened lines are of the postero-medial border of the pleura.

Incidentally, it may be stated that in the abdomen a lateral deviation of the line of the psoas muscle may help us to detect the site of an acute abscess, or a chronic abscess before calcium has been deposited within it. For anatomical reasons this line of the psoas may appear to be continuous with that of the postero-medial border of the lung.

Points in Differential Diagnosis

Because of this common appearance of the dorsal tuberculous paravertebral abscess there is a tendency to diagnose all fusiform deviations of the postero-medial border of the lung as tuberculous in origin, but appreciation of the anatomical features I have described which give rise to these shadows induces further discrimination. Thus neoplasm, both primary and secondary, may cause collapse and an increase in the transverse diameter of the diseased vertebral body: this will cause a lateral deviation of the postero-medial border of the lung, which will be increased, if there is proliferation of neoplastic cells or if associated with haemorrhage, to such an extent that it may resemble a paravertebral abscess. It should be remembered, however, as a feature in differential diagnosis, that neoplasm appears to spare the disks even though all the vertebral body is destroyed.

Fusiform paravertebral expansions have been seen at the site of pneumococcal, typhoid, and paratyphoid abscesses. In these the destructive changes are more frequently present in the disk, which appears to collapse, and within a few weeks the postero-medial border of the lung is straightened out again. The vertebral bodies ultimately fuse. In the acute phase of vertebra plana the involved body is surrounded by fusiform expansion, which within a few weeks gradually disappears, leaving the disk apparently intact but the elements of the vertebral body compressed to a quarter or a third of the normal depth. In Paget's disease that is localized to one or more dorsal vertebral bodies the postero-medial border of the lung is deviated laterally by the expansion of the bodies. In osteochondritis of the spine in infants and adolescents some degree of thickening of the tissues adjacent to the vertebral bodies occurs, and the medial border of both lungs may become apparent just lateral to the border of those bodies; but in this there is no localized fusiform expansion.

In one case rupture of the posterior wall of the aorta was associated with haemorrhage into the areolar tissue surrounding the vertebral bodies: an appearance simulating a paravertebral abscess was produced. Any inflammatory or neoplastic proliferation within the vertebral body or the areolar tissue surrounding it may produce changes such as have been described, and it may be necessary to seek elsewhere for a clue to the identity of the organisms and cells producing the displacement of the lung. Empyema localized to this site would also push the lung laterally.

Summary

The line of demarcation formed at the flattened postero-medial border of the lung by the sharp contrast between the relative radiotransparency of the lung and the radio-opacity of the vertebral tissues is of valuable diagnostic significance in cases of backache.

The anatomical investigations which contributed to the discovery of the cause of this radiographic sign were carried out in the anatomy department of the University of Birmingham with the kind permission and assistance of Prof. C. V. Smout.

Medical Memoranda

A Case of Bilateral Bell's Palsy

Double Bell's palsy has always been looked upon as an uncommon phenomenon. Jellife and White (1935) consider it rare, as do Osler and McCrae (1935), Price (1941), Savill (1939), and Walshe (1941). Numerous cases of facial diplegia have been quoted, but the majority of them have been due to some condition such as epidemic encephalitis, trauma, or a lesion at the base of the brain. Bashford and Wilson (1918), Holmes (1917), and Viets (1927) have recorded numerous cases of facial diplegia due to other causes. Currier (1928) discusses facial diplegia and records two cases, but these are not of the type commonly called bilateral Bell's palsy. Most authorities now agree with Patrick (1916) that Bell's palsy is due to an infection elsewhere plus exposure to cold, although the infection is not always apparent.

CASE HISTORY

An electrician aged 17 was seen at the out-patient department of the Royal Infirmary, Sunderland, on Dec. 9, 1940. About a fortnight previously he was unable to whistle; food had a tendency to drop out of his mouth; and when he washed himself the soap got into his eyes. He stated that he had suffered from a catarrhal "cold" about a week previously. There was no history of ear trouble, whether deafness, pain, or discharge.

On examination both sides of the mouth were drooped, furrows of the brow were indefinite, naso-labial folds on both sides tended to be obliterated, and there was a general loss of expression in the face Both eyes could be opened against the patient's efforts to keep them closed, the left side perhaps more so than the right. He was unable to close both eyes completely, and wrinkling of his brow was poor. He was unable to whistle or blow out either cheek Attempts to show his teeth were poor, and the mouth tended to be drawn to the right side to a slight degree. No loss of sensation was detected over the face. Taste on the anterior two-thirds of the tongue was normal. There was no marked sensitivity to loud noises. The other cranial nerves were normal, as were the fundi. The central nervous system showed no other abnormality, and the circulatory, respiratory, alimentary, and urinary systems were normal. Radiographs of the skull revealed nothing unusual.

Examination of the cerebrospinal fluid showed: No cellular increase; protein 50 mg. per 100 c.cm.; negative Wassermann reaction; Lange curve, 0123444421. A blood count gave Hb 84%; R.B.C. 4,300,000; C.I. 1; W.B.C. 7,200—polymorphs 52%, lymphocytes 35%, eosinophils 6%, large mononuclears 7%, basophils 0. The red blood cells were normal in size. The electrical reactions were as follows: Brisk faradic response in both sides of the face; galvanic response normal; slightly sluggish on right side of face. Mr. Jowett of the E.N.T. department reported that no abnormality was detected in the ears and that hearing was normal.

The patient's condition improved gradually, and by Dec. 21 it had practically cleared up. The fact that his electrical reactions remained normal, the paralysis was not complete, and sensation in the tongue was normal bears out the usually accepted idea that recovery will occur rapidly. This was so in the present case.

Re-examination, March 21, 1942.—During the past year he has felt well and has noted no abnormality with regard to his face. He has continued at work without a day's absence. The pupils are equal, the eye movements full, and the power in both eyelids normal. He can wrinkle his brows normally, and the lines of his face on both sides are well marked. He can whistle, and the sensation of his face and tongue is normal.

A. A. McINTOSH NICOL, M.D., M.R.C.P.
Hon. Physician, Royal Infirmary, Sunderland.

X-ray Investigation of Stridor in a Child

Histories of illness in childhood are of necessity obtained second-hand. Although parents are keen observers, it is inevitable that vital facts in a story may be omitted simply because the child was alone when some particular episode occurred. This applies particularly to the habit children have of inserting all sorts of objects into their various orifices. Then it is that *x*-ray examination may reveal an unsuspected foreign body, and provide the answer to a puzzling train of symptoms and signs. The following case shows how radiographs revealed the cause of a tracheal stridor which had been present in a child for a period of over one year.

CASE HISTORY

A boy of 2½ years was brought to the Princess Elizabeth of York Hospital for Children on account of stridor. The history was that he was well until 13 months before admission, when he had choked over the first mouthful of his afternoon meal and had vomited it. Immediately following this he had been unable to swallow anything but fluids for the ensuing 10 days, after which the power to swallow solids had gradually returned, accompanied by the development of a stridor. He had had the stridor constantly since then, and the mother had noticed that it had been more marked for the last two months. There had been no dysphagia after the initial 10 days, and in all other respects he seemed well.

Ten months after this episode the child was admitted to another hospital for radical cure of a hydrocele. Whilst awaiting operation he had developed otitis media, so the operation was postponed. Later his tonsils and adenoids were removed, and he was finally discharged after a total of 11 weeks, without operation having been performed. Radiological investigation of the stridor was not carried out, although its presence at that time was noted, and was, in part, the reason for postponing operation.

On investigation, 13 months after its onset, the stridor was found to be constant, chiefly inspiratory, and increased by activity. The child was well nourished, and no abnormality was to be seen in the pharynx. The chest was clear. There were a bilateral chronic otitis media and a right hydrocele. Radiographs showed a cog-wheel 3/4 in. in diameter lying in the coronal plane at the level of the sterno-clavicular joint and posterior to the trachea, which was narrowed to a slit at this point. The supposition that the wheel was in the lumen of the oesophagus was confirmed by a barium swallow, which showed the barium stream being divided into two by the hub of the wheel. Under general anaesthesia the wheel was successfully removed by grasping it in crocodile forceps passed down an oesophagoscope. Its removal was followed by the discharge of a few c.cm. of foul-smelling pus and some fresh blood.

Post-operative progress was satisfactory. The child was given no fluid by mouth for 24 hours, an intravenous drip glucose-saline being maintained for this time. Thereafter fluids by mouth were started in small quantities and rapidly increased. There was no dysphagia, and no pyrexia after the first 24 hours. The stridor gradually decreased, and was practically absent when the patient was discharged three weeks later. A barium swallow given two weeks post-operatively showed considerable residual deformity of the oesophagus, but no obstruction. A follow-up is to be carried out to detect the possible onset of a stricture.

I am much indebted to Mr. C. P. Malley for permission to report this case, and to Dr. C. Hilliard of Hertford County Hospital for the radiographs taken.

Reviews

ANAESTHETICS AFLOAT

Anaesthetics Afloat. By Surg. Lieut.-Commander Ronald Woolmer, R.N.V.R., B.M., B.Ch., D.A. With an introduction by Surg. Capt. H. D. Drennan, D.S.O., R.N. (Pp. 120; illustrated. 6s.) London: H. K. Lewis. 1942.

A surprising amount of sound and useful information is collected here. The author has a pleasant style and gives essential information without weighing this down with unnecessary details. From his own experience of anaesthesia at sea he deals clearly with special problems that may be met with there, and this practical teaching is invaluable to those who must work under emergency conditions. The chapters on "Mishaps and Difficulties in Anaesthesia," on "Anaesthesia in Relation to War Wounds, Injuries, and Shock," and on "Mode of Anaesthesia for Various Operations" are especially good. Full details of the preparation of patients for general anaesthesia are given, and the chief methods of spinal analgesia and the most useful types of local analgesia are described and illustrated.

Among the few controversial points are these: Many anaesthetists would consider that this author's advice that morphine for premedication be given three-quarters of an hour before operation would lead to respiratory depression during the induction, in cases where ether is used, and it is now more commonly taught that morphine should be given one and a half hours before operation. The instruction that a patient who has developed ether convulsions should be placed in the Trendelenburg position is contrary to the usual teaching, which advises the head-up (anti-Trendelenburg) position. Then, whereas the correct warning is given not to use general anaesthesia for operation for peritonsillar abscess, yet it is surprising to read that local anaesthesia should be achieved with the ethyl chloride jet. One wonders why a cocaine spray is not advised, since the average patient would inhale enough ethyl chloride to become unconscious.

The usefulness of intravenous barbiturates is rightly stressed, but the statement about evipan and pentothal, that "both drugs, however, have a very high margin of safety," true though it is for the experienced person, may give an inexperienced anaesthetist undue confidence with them. Very sound advice is included as to the care with which endotracheal intubation should be performed. The instructions on the treatment of a patient during operation under spinal analgesia are excellent, and could be read with great advantage by those anaesthetists, and also surgeons, who habitually disturb the patient by asking him if he is feeling pain.

This book will really fit into the pocket; it has a special usefulness in time of war, and the author is to be congratulated on this valuable addition to the literature.

PROBLEMS OF BLOOD TRANSFUSION

Blood Substitutes and Blood Transfusion. Edited by Stuart Mudd, M.A., M.D., and William Thalhimer, M.D. (Pp. 407. $5.00 post paid or 27s. 6d.) Springfield and Baltimore: Charles C. Thomas; London: Baillière, Tindall and Cox. 1942.

This "symposium monograph," edited by Stuart Mudd and William Thalhimer, is based on papers read at the annual meeting of the American Human Serum Association held in 1941 and revised and brought up to date in the spring of 1942. The subjects discussed include aetiology and mechanisms of secondary shock; methods of preservation of plasma and serum; haemoglobin, serum albumin, and casein digests as blood substitutes; storage, transportation, and administration of whole blood with special reference to iso-agglutinins and group-specific substances; and therapeutic experiences with serum and plasma. There is little reference to work carried out in England in both the preparation and use of blood derivatives. In the last two years literally thousands of litres of both serum and plasma have been prepared and administered in this country. It is odd, therefore, to read papers devoted to an account of the administration of 250 c.cm. of concentrated serum to one patient.

In spite of the extensive experiences of observers here showing that haemoconcentration does not occur to any marked degree in traumatic shock, Virgil Moon still insists on its significance in this condition. It is of interest to find several groups of investigators emphasizing that serum appears to be of equal value to and no more toxic than plasma, a point of view which, though held here by many workers, has not hitherto been accepted in the U.S.A. Elliott and Marsh, as the result of clinical trial, conclude that "the clotting of blood does not impart toxic properties to its serum"; while Self and Scudder state: "We favour the use of liquid pooled human serum over liquid plasma . . . the increase in the incidence of reaction to serum is not severe enough to warrant withholding serum for this reason. We feel that just as patients with leukaemia or aplastic anaemia are prone to react to blood transfusions, so are patients suffering from hypoproteinaemia or having abnormal protein patterns particularly liable to reaction from serum or plasma infusion. . . . Our experience suggests that if a patient reacts to serum he is likely to react also to any blood substitute. . . . It is our feeling that patients in shock are much less prone to react to serum or plasma than other patients." This latter point has often been noted by English observers, but there is at present no explanation of it.

Witebsky and his colleagues contribute an interesting paper on the neutralization of iso-agglutinins anti-A and anti-B in O (IV) blood by means of the addition of the isolated group-specific substances. These substances were isolated either from the saliva or hog tissue in the case of A, or from gastric juices or horse tissue in the case of B. Those workers have given 100 transfusions of O blood to which these group-specific substances were added to reduce the titre of the normally occurring iso-agglutinins. It is clearly too soon to evaluate the practical significance of these observations. A discussion on the bacteriological control of the preparation of plasma by workers at Columbia University will be of particular value to those who have been concerned with similar problems elsewhere. The authors conclude that "at present to the best of our knowledge there is no preservative which when added to human plasma or serum will ensure sterility of the final product. The best safeguard for the sterility of these blood substitutes is filtration through bacterial filters."

Though this symposium contains much that will stimulate and interest specialists, it is not recommended to the general and uncritical reader who wishes to gain up-to-date knowledge of transfusion problems.

A MEDICAL PSYCHOLOGIST UNBENDS

Out of Working Hours: Medical Psychology on Special Occasions. By Henry Yellowlees, M.D., F.R.F.P.S., F.R.C.P., D.P.M. (Pp. 152. 8s. 6d.) London: J. and A. Churchill. 1943.

Dr. Henry Yellowlees once remarked that he was brought up on the Bible, Shakespeare, and *The Pilgrim's Progress*—no bad foundation. In his *Out of Working Hours* there is ample evidence of that upbringing. Thus in his Morison Lectures on "The Problem of Adolescence" he makes effective use of the third chapter of Genesis as a parable of that problem. The "return to the garden" as the symbol of a craving for regression is beautifully expressed by H. G. Wells in his story *The Door in the Wall*, and the two provide an interesting scientific and artistic parallel on the same theme. These lectures were given before various audiences, usually non-medical, and are designed to explain what medical psychology is aiming at. The author quotes with approbation Dr. Bernard Hart's remark that "nothing but hopeless confusion can result when one mixes the language of brain cells and nerve fibres with that of thought and conduct"—a warning too often disregarded. In his entertaining lecture to masseuses entitled "Word and Action" Dr. Yellowlees gives an imposing list of things "thou shalt not" talk to the patient about, but his positive recommendations are less precise. His lecture to sister-tutors on "A Little Brief Authority" contains admirable hints how not to treat their probationers. This little volume is brought pleasantly to a conclusion by an oration before the Harveian Society of Edinburgh. Doubtless the truth about Harvey lies somewhere between Aubrey's picture of the "cholerick little man" and the orator's idealized portrait, but we are satisfied that the latter is nearer the mark. Common sense, good humour, and pungent wit characterize all these confessedly lighter efforts of the author.

Notes on Books

The third edition of Mr. G. F. Gibberd's excellent *Short Textbook of Midwifery* is now available. The author has deliberately avoided new material of doubtful value and has concentrated on that concise presentation of sound orthodox obstetric practice which has already made this little book most popular with students and practitioners. Its popularity is well deserved. It is published by J. and A. Churchill at 21s.

Preparations and Appliances

A NEW FORM OF SIGMOIDOSCOPE

Surgeon Rear-Admiral Cecil P. G. Wakeley, C.B., D.Sc., F.R.C.S., writes:

Since first using "Colite" instruments some four years ago considerable improvements in design, construction, and power of illumination have been achieved. Hitherto these instruments have been made in solid form only as retractors, tongue depressors, speculae, etc. Vann Brothers have now produced tubular instruments such as sigmoidoscopes, proctoscopes, and direct-vision cystoscopes.

The main features of the sigmoidoscopes (Fig. 1) are that the source of light is placed outside the tube, allowing an unobstructed view, freedom of operation, and safe use of diathermy instruments, as the material is a perfect non-conductor of heat and electricity. The cold light travels along the wall of the instrument and escapes at the distal end, showing the object under examination in a plastic form and natural colouring. For use with the sigmoidoscope I have had made a stainless-steel inspection mirror (Fig. 2) with a graduated stem. This mirror is of great practical utility, for it enables ulcers, fissures, polypi, and carcinomata to be detected at an early stage. These various conditions can be clearly seen through the wall of the sigmoidoscope, thereby greatly facilitating an early and accurate diagnosis. A further advantage is that once the instrument is introduced the complete examination can be made by moving the mirror inside the tube, thus eliminating discomfort to the patient.

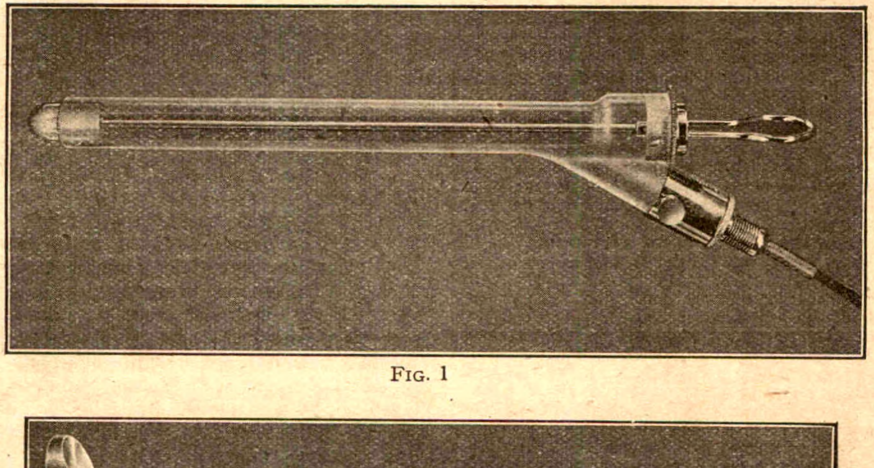

Fig. 1

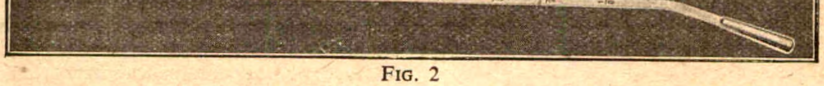

Fig. 2

For all practical purposes this apparatus is unbreakable and can be sterilized by boiling. It should prove to be a valuable addition to the surgeon's equipment of really "worth-while" instruments. It is made in two sizes—13/16 in. and 15/16 in. external diameter—by Messrs. Vann Brothers, 63, Weymouth Street, London, W.1.

ACCURATE HAEMOGLOBINOMETRY

Until now clinicians and pathologists alike have viewed with some justifiable suspicion reports on such common and apparently simple investigations as haemoglobin determinations and red cell counts when the signature to the report was unfamiliar. This suspicion was justified because of the lack of standardization of the methods employed and the uncertain calibration of the commercial standards available. Thus one worker may use a Haldane instrument in which 100% = 18.5 vols.% O_2 = 13.8 g. Hb per 100 c.cm. of blood; a second might use one of the modified Sahli methods with 100% = 19.4 vols. % O_2 = 14.5 g. Hb per 100 c.cm. of blood; a third a Newcomer, with 100% = 21.4 vols. % O_2 = 16 g. Hb per 100 c.cm. of blood; and a fourth the original Sahli of 100% = 23.2 vols. % O_2 = 17.3 g. Hb per 100 c.cm. of blood. Each of these might have been accurately standardized or not, and in the latter case the error might easily reach 20%. The habit of reporting haemoglobin estimations in terms of grammes Hb per 100 c.cm. as well as in percentages has become more usual during the last few years, and this provides a most valuable check on the meaning of the term "100% Hb." Nevertheless many workers, especially those in small laboratories, and even in the larger ones since the war, have available neither the apparatus nor the technical skill required accurately to determine the haemoglobin content of blood either by the oxygen capacity or by the blood-iron method, so they are forced to rely on the colour standards commercially available. It is well known that these "standards" are reliable neither for accuracy of calibration nor for long life.

The British Standards Institution and the Analytical Methods Subcommittee of the Traumatic Shock Committee of the Medical Research Council—whose report on haemoglobinometry appears in the opening pages of this issue—therefore deserve the thanks of all practitioners for their attempt to end this unsatisfactory state of affairs by issuing a specification for a British standard clinical haemoglobinometer,[1] and arranging with the National Physical Laboratory (Teddington, Middlesex) for accurate calibration of the instrument. The pattern chosen is the original Haldane instrument, still used by most clinical pathologists in this country and capable of an "accuracy" of ± 2% on the Haldane scale. The 100% of this instrument corresponds to an oxygen capacity of 18.5 vols. % or to 13.8 g. Hb per 100 c.cm. The N.P.L. is prepared to accept colour tubes, dilution tubes, and 0.02-ml. pipettes for testing for conformity with specification or to provide a detailed statement of errors. It is suggested that colour tubes should be checked by the N.P.L. every six months. The cost of certification is not excessive—£1 for the colour tube and a few shillings for dilution tubes and pipettes.

Some five years ago the B.S.I. issued a specification (No. 748/1937) for haemocytometer counting chambers with Neubauer and Bürker rulings, cover glasses, and pipettes, the permissible error being ± 5% for the counting chamber and ± 3% for the pipettes. These also can be checked by the N.P.L. for conformity with specification or to provide a detailed statement of errors, the cost in the latter case being £1 7s. 6d. per chamber and a few shillings for the pipettes. If instruments certified to conform with specification are used the possible variation between reports is still considerable. If the errors were cumulative, but of opposite sign, a blood which truly had Hb = 100% and R.B.C. 5,000,000 may be reported by one laboratory as "Hb 95%, R.B.C. 5,400,000 per c.mm., colour index 0.88," and by a second as "Hb 105%, R.B.C. 4,600,000 per c.mm., colour index 1.14." Usually, of course, errors tend to cancel each other, but it is obvious that a detailed statement of errors for each haemocytometer chamber, for each haemoglobinometer, and for the accompanying pipettes should be obtained and the necessary correcting factor be applied. Even then the significance of differences of cell count must not be exaggerated, for the coefficient of variation of sampling is of the order of 5%, and counts differing by less than 7% or 300,000 for counts in the range 4,000,000 to 5,000,000 cannot be regarded as significantly different. Higher accuracy can be obtained only by increasing the number of cells counted in several different preparations, and for general clinical use this would require labour excessive in comparison with the results achieved. The general adoption of instruments certified by the N.P.L. for determining blood counts should, however, make it possible to accept blood counts from different institutions without suspicion. This is of great importance when patients are transferred from one hospital to another some distance away.

Now that reasonably accurate instruments are available it is surely desirable that those indices introduced by Wintrobe—the mean corpuscular volume and the mean corpuscular haemoglobin concentration—should come into general use to amplify the colour index. Considerably greater certainty in classifying obscure anaemias can be attained by their use, particularly in the anaemias associated with pregnancy and the puerperium, where true megaloblastic reactions with a raised mean corpuscular volume may accompany a normal or subnormal colour index. The M.R.C. Subcommittee recommends the general adoption of Wintrobe's technique for determination of red cell volume, using either heparin or Wintrobe's anticoagulant. Screw-capped 1/4-oz. bottles (bijou bottles) with a capacity of 6 c.cm. are now in general use, and these can be heparinized to contain 50 Toronto units to prevent the coagulation of 5 c.cm. blood (for about a farthing), so that the question of cost should not in future deter pathologists from using heparin for most haematological work; the need to measure with some accuracy 5 c.cm. of blood into tubes prepared with Wintrobe's anticoagulant is thus avoided.

The British Standards Institution proposes to place the medical practitioner still further in its debt by standardizing an acid haematin (Sahli) instrument in the same way, so that those who determine haemoglobin values in their patients' homes, or for other reasons have no coal gas or carbon monoxide available, will be at no disadvantage compared with their better-equipped colleagues. It is much to be hoped that it will complete its work by issuing a specification for a haemoglobinometer of the Wintrobe-Hellige (Hellige "Neoplan") type, using a glass wedge, for in the experience of many this is far the most satisfactory instrument for general clinical work.

PHYSIOLOGY OF CLOTHING

A century and a half ago Count Rumford suggested that the hygienic properties of clothing merited serious scientific study. Included in the aims of the Royal Institution was the instruction of the public in the proper practice of the domestic arts, particularly those relating to "the management of heat and the saving of fuel." Among these the application of the laws of heat to clothing and fuel economy was specially mentioned.[1] That these very subjects have now become the everyday practical concern of every citizen hardly needs emphasizing; and besides these topics there are in modern war, as Sir Leonard Hill has graphically described in his recent article,[2] a considerable number of situations which call for the provision of highly specialized clothing. Wearing apparel for fighting personnel must be planned as protection against a variety of external agencies—wind, water, dust, ice, gas, and fire, as well as the climatic extremes of heat and humidity—and, withal, the garments have to be reasonably light, comfortable, strong, and serviceable. As Sir Leonard Hill says, on all these occasions the provision of the appropriate clothing requires as a basis the application of "physiological common-sense." This means particularly an appreciation of the facts of heat regulation in the human subject. But, while it is largely true that specialized protective garments have still to be devised and developed empirically, nevertheless since Count Rumford's day there has been a steady progress in the scientific study of clothing. The most notable contribution came from Max Rubner and his school some thirty years ago.[3] The Munich workers systematized those clothing properties having physiological and hygienic significance and made many observations on the comparative value of different fabrics under a variety of conditions. But for the most part these valuable studies were concerned with clothing materials off rather than on the human subject. Here it may be of interest to note that the most remarkable nonsense written under the guise of science has come in this field from Nazi Germany, where the study of textiles has been pursued by interested parties as a racial issue—thus wool is said to be "superior" to synthetic fabrics because the ancient Teutons were a "wool-people."[4]

After Rubner an advance was made by Hill, who was able to assess the value of garments for particular purposes (e.g., for shipwrecked sailors) without recourse in the first instance to prolonged testing on the human subject[5]; his katathermometer could be provided with a wet or a dry clothing surface, and its rate of heat loss was easily measurable. Rubner, who combined so well the pursuit of pure and applied science, was also a pioneer in the study of heat regulation of the human subject. It is this branch of physiology which of recent years has undergone a notable advance, due mainly to refinements in technique in the laboratories of du Bois, Bazett, and specially of Winslow and his colleagues.[6] The latter have established not only the principles but many of the quantitative data of heat regulation in relation to a wide range of environmental conditions. With their data, and particularly their methods, the thermo-regulatory role of clothing can be understood in a fairly exact way. It is now possible also to formulate the insulation requirements of clothing for a vari
external air and radiant temperatures, taking into ac
also the level of heat production due to work.[7] S
on the physiology of clothing have also been proc
in the London School of Hygiene.[8] Such studi
making practicable the establishment of rational sta
of clothing at least as regards thermal properties.
far more than is the case with nutrition, thermal ins
standards can be only a rough guide when applied t
vidual requirements. As a basis for clothes rationin
standards would have to be greatly modified by h
considerations—necessity for changes of clothing for
liness, durability, special clothing for work, etc.—a
as by social factors which affect the range and
of clothing. Nevertheless, the need to take clothin
account (e.g., in budgetary surveys) is well apprecia
social investigators, although this has to be done
quite arbitrary basis.[9] The objective evaluation of cl
might well prove of value also in connexion with
surveys of such diseases as rheumatism and tuberc
As in the case of food, income level has a definite inf
on the amount and type of clothing bought.[10] E
it were desired to use as a reference line the warm
quirement with regard to, say, the coldest prevaili
temperature and wind of particular localities, in p
a further problem would still face the field worker
is the actual assessment of the probable insulating
of the garments when worn. The value of easy me
ments such as thickness, or weight per unit of s
area, as guides in this direction requires careful
sideration.

In the laboratory the assessment and comparis
fabrics on a physiological or near-physiological bas
more practicable proposition, particularly with the
provided by the newer studies of thermal regulation
human subject. Such investigations have of course
pursued by a large number of workers, particularly
Rubner's time,[11] and they are to-day assuming a
importance. The introduction of many new and
synthetic textile fibres demands that comparisons wi
time-honoured fibres be conducted largely on a more
physiological and hygienic basis. For the comparis
fabrics much attention has of course to be focused o
heat-retaining properties; but the reactions of the fib
the fabric to moisture are also of importance, no
with regard to manufacture but physiologically as we
the latter field a number of questions remain large
answered. There is the question of the moisture di
permeability of clothing since evaporative cooling
important channel of heat dissipation. Of more i
perhaps, is the old-standing problem of the moistu
gain properties of different fibres. The heat of "sor
in relation to, say, resting heat production is a signifi
large amount when garments are transferred from
spheres of a low to one of high humidity[12] and th
relations are of the right order.[13] But these are stud
the isolated materials. On the human subject there i
doubt that these effects would be significantly altered
humidity levels and gradients prevailing in the garme
worn. This stresses again the primacy of physiol
investigation for providing a sure basis for the sci
study of clothing.

THE NUFFIELD FOUNDATION

Lord Nuffield has intimated his intention to hand over to trustees his shareholdings in the Nuffield organization to the value of £10,000,000 as a capital fund for the founding of a charitable trust to be known as "The Nuffield Foundation." He has appointed the following managing trustees to administer the income from the fund: Sir William M. Goodenough, Bt. (chairman); Sir John S. B. Stopford, M.B.E., F.R.S. (vice-chairman); Prof. F. L. Engledow, C.M.G., M.A., B.Sc.; the Hon. Geoffrey C. Gibbs; Sir Hector Hetherington, M.A., LL.D.; Sir Henry T. Tizard, K.C.B., F.R.S.; Miss Janet Vaughan, D.M., F.R.C.P. The objects of the Trust have been given as follows: (1) Medical research and teaching; (2) the organization and development of medical and health services; (3) scientific research and teaching in the interests of trade and industry; (4) the pursuit of social studies; (5) the care and comfort of aged persons. Great Britain and Northern Ireland will be the terrain normally covered by the Trust's activities, but provision is made for any projects that may especially affect the Empire, and in connexion with the first and third items above scholarships and other assistance will be available for Empire students. Another provision is that those of Lord Nuffield's trusts already in being may benefit from the income of the new foundation.

British medicine may indeed count itself fortunate that at this moment in its history, when so many new projects of science and of administration are in the air, it has at its elbow a man who is able to bestow on it such princely benefactions with such a sure vision of what the needs of medicine are. The endowments at Oxford, with the recent establishment there of an Institute of Social Medicine, the Nuffield Provincial Hospitals Trust, and now this new great gift, put this country, and more especially the doctors of this country, profoundly in Lord Nuffield's debt and secure for his name a perpetual place on the roll of the great benefactors of medicine.

PRIMARY ATYPICAL PNEUMONIA, AETIOLOGY UNKNOWN

During recent years much interest has been shown in acute respiratory infections associated with atypical pulmonary lesions and apparently not due to the common respiratory organisms. Numerous authors in a steadily increasing literature have described the condition under the names of "virus pneumonia," "acute pneumonitis," "atypical bronchopneumonia," etc. The Director of the Commission on Pneumonia (Board for the Investigation and Control of Influenza and Other Epidemic Diseases)[1] in the U.S. Army has suggested that these cases now be separated in their classification from other pneumonias and be called "primary atypical pneumonia, aetiology unknown." In a recent article Dingle and Finland[2] ably review the whole subject and append some sixty references.

In this country the condition has been recognized for some years, but particular interest is focused on it at present owing to its occurrence among troops. It is difficult to say whether the disease is actually on the increase here or whether the more frequent and liberal use of *x*-ray diagnosis is disclosing cases which were previously passing unrecognized. An outbreak of atypical "influenzal pneumonia," described by Herxheimer and McMillan,[3] in a boys' school in Devon appears to be a similar condition. In America the disease has been reported mainly by military and student health doctors, who deal with groups of young adults and adolescents, among whom it is prevalent. An account of an outbreak in Cornell University is given by Smiley and others,[4] who draw attention to the ease of transmission of the disease. Young doctors and nurses in contact with cases in hospital have also figured prominently in the records. It seems possible, however, that the condition is not limited to this age group, and cases have been described from infancy to old age. Ramsay and Scadding[5] in 1939 reported apparently similar attacks in children, and more recently two epidemics among young infants have been recorded by Adams, Green, Evans, and Beach.[6]

Diagnosis may not be easy, particularly on clinical evidence alone, for the pulmonary changes revealed by *x* rays are often far more extensive than would be supposed from the clinical findings. The onset is insidious with fever, cough, malaise, headache, and chilliness, which may be preceded or accompanied by sore throat or nasal discharge. The degree of prostration is variable; so also is the temperature, which may be between 99° and 105° F. The pulse rate is ordinarily within normal limits, but may be low. The respiration rate is commonly unchanged. Pulmonary signs, if present at all, are slight, and may be limited to fine moist rales or adjacent areas of resonance and dullness. Such chest signs as are found may change daily or even hourly. The white cell count is normal in most cases. Sputum is scanty at first, but later becomes more productive and mucopurulent. Usually the course of the illness is mild and lasts 2 to 3 weeks, but it may be 8 weeks or even longer before complete recovery occurs and the chest is clear by physical and *x*-ray examination. Severe and, more rarely, fatal cases do occur. Complications include cerebral disturbances, depression, mild encephalitis, meningismus, thrombophlebitis of limbs, and pulmonary infarction. Treatment is symptomatic, and sulphonamide drugs have no beneficial effect. Definite evidence of pulmonary involvement is usually discovered by *x*-ray examination of the chest. Lesions are often found within the first few days, and the first change is an increase in the size of both hilar shadows, which is later followed by an infiltration extending outwards towards the periphery of the lung fields. The infiltration usually appears as patchy densities, mottling, or fine hazing. Such lesions commonly occur in the lower lobes, but may be found anywhere in either lung. In about 20% of the cases they are bilateral. Though the radiographic picture is fairly characteristic, it may be confused with that of pneumococcal pneumonia, bronchopneumonia, acute bronchitis, tuberculosis, pulmonary abscess, metastatic infiltration, and known virus and rickettsial diseases—e.g., Q fever, psittacosis, or influenza.

The aetiology of the disease has not been established. The usual laboratory procedures have yielded entirely negative results, and organisms isolated from the nose, throat, and sputum are generally those found in the respiratory tracts of normal individuals. This, together with the fact that the disease is communicable and that it is unaffected by sulphonamides, has led to the belief that it is due to a non-bacterial infection. Numerous attempts have been made to isolate rickettsias or viruses from the patients. The only workers to meet with much success have been Weir and Horsfall,[7] who reported the isolation in chick embryos and in the mongoose of a filterable virus obtained from each of four patients with the disease. They also found that this agent was neutralized by convalescent serum. Evidently further work is required to determine the aetiological agent, and a number of investigations are being carried on at the present time.

INFLUENCE OF DIET ON RENAL VOLUME

Despite the classical experiments of Barcroft on the explanted spleen, little use has been made of this experimental method in the study of other organs. Allen and Cope[1] have recently been experimenting on dogs with explanted kidneys, and were able to observe several facts which may have a bearing on the question of hypertension and its treatment. Their main conclusions are as follows. The ingestion of salt and water causes an acute increase in kidney size and rise of blood pressure. These effects may be sustained so long as the high salt diet is continued, but return to normal when an ordinary diet is resumed. The increase in kidney size is therefore thought to be due to hyperaemia. In protein feeding experiments there is little immediate increase in size of the kidney, and the usual effect on blood pressure is to reduce it. Prolonged protein feeding, however, gives rise to enlargement of the kidneys which tends to remain and appears to be a true hypertrophy. It is not clear from the paper referred to what was the effect of prolonged protein feeding on the blood pressure. A further outcome of the experiments is that variations in blood pressure may occur independently of any change in the size of the kidney. The reverse may also be the case. Administration of ether caused a sharp reduction in kidney volume, again emphasizing the possible inaccuracies of experiments made under anaesthesia. These experiments show, therefore, that the kidneys, like the spleen, undergo daily and hourly variations of size during their normal activity. The kidneys of hypertensive dogs were in general more sensitive to changes of diet than those of animals with normal blood pressure. The results also seem to give point to salt restriction in the treatment of hypertension.

"ANY QUESTIONS ?"

General practitioners are exceptionally busy people and are confronted daily with questions of health and ill-health that demand immediate answers. Even when there is time for reflection and opportunity to postpone the answer, it is not always easy to find it ready made in one of the books on the consulting-room shelves. In any event, each case of ill-health presents an individual problem in which the stock answer and the stock mixture are not always the most satisfactory. It is natural, therefore, that the practising doctor should look to his weekly medical journals for help in the day-to-day conduct of his work, with, perhaps, expectations that are unduly sanguine. One result is that many do not read their weekly medical journals with as much interest as they read their daily and Sunday newspapers. The overworked practitioner might well retort that the latter are written in a simple and attractive way, so as to lighten the task of acquiring knowledge. There is no disputing this, but news and views in the popular press are treated only on the most superficial plane, and rarely in a way to provide solid information. Medicine is an exacting profession, if for no other reason than that the sciences on which it is founded are growing rapidly and providing the practising doctor with new technical equipment and knowledge. One of the disadvantages of general practice as it is conducted to-day is that it leaves the practitioner with very little time to spare and, indeed, very little energy to make use of that spare time in a way profitable to himself. Let us hope that in the medical world which so many people are now busily planning for the future the planners will not for-
get this all-important question of leisure. We fully sy
thize, therefore, with the feelings of the tired doctor f
with the toil of reading an article three or four p
long, packed with close argument, when what he r
wants to know is how to get rid of that troublesome
complained of by Mrs. X, and what advice he sh
give to Mr. Y for his pruritus. Before the war, as rea
may remember, we tried to meet this difficulty by pub
ing every week specially commissioned articles under
heading of "Treatment in General Practice." That
met a demand was made clear by appreciative corres
dence that reached this office, and by the successful
of the four volumes of collected articles published
by Messrs. H. K. Lewis. The war interrupted the l
term programme that had been planned, and progre
restriction on space since the war has not made easier
task of catering for the needs of the various grou
research workers, consultants, specialists of many ki
public health officers, as well as general practitione
who go to make up the readers of this *Journal*. It
be remembered that this is a scientific newspaper,
one of its duties is to offer a place for the publicatio
original scientific communications that form the gro
work for the practical advances of to-morrow.

For many years space has been provided at the en
the *Journal* for questions asked by doctors, in the h
that one or more readers will come forward with hel
answers. Occasionally the Editor has sought the view
an authority, and has published these with the ques
asked, as in the case of Income Tax queries. The la
method will be more widely used, and from now on
proposed to print, along with selected questions, ans
to them from selected experts. That part of the *Jou*
may occupy more and more space as time goes on,
for the duration of the war it will be at the mercy
the Paper Controller. It will also be limited by the n
ber and relevance of the questions submitted. But an e
will be made to turn the Queries and Answers colu
under another heading, into one of real help to the pra
ing doctor, especially the G.P.

SIR FARQUHAR BUZZARD

Sir Farquhar Buzzard will retire in April from the Re
Professorship of Medicine at Oxford, a chair he has oc
pied with great distinction since 1928. During that ti
largely through his vision and wise counsel, there has b
an unparalleled development of the Oxford Medi
School, notably in connexion with the Nuffield Instit
for Medical Research, the Provincial Hospitals Tr
and the wartime organization of clinical teaching at
Radcliffe Infirmary. Outside the University he has d
national work of the first importance in the promotion
schemes for co-ordinating and nationalizing hospital
medical services. Sir Farquhar Buzzard's activities h
not been restricted to purely medical work, for he has tal
a keen interest in all that pertains to the welfare of
University in various academic appointments. His frie
and colleagues feel that his great services should be co
memorated, in some permanent form, in Oxford. A rep
sentative committee has suggested as suitable memori
the painting of his portrait and, should sufficient additio
donations be received, the endowment of a Buzz
Scholarship or Prize in Medicine. This project will m
a wide appeal to members of the British Medical Assoc
tion, over which Sir Farquhar presided at the success
Annual Meeting in 1936. Donations may be sent to
Vice-Chancellor of the University, Oriel College, Oxford.

SCIENTIFIC FREEDOM AND SOCIAL MEDICINE

BY

GEOFFREY BOURNE, M.D., F.R.C.P.

The Social Security plan proposed in the Beveridge report involves the assumption of "comprehensive health and rehabilitation services" (Part VI, para. 409). It is stated that "a comprehensive national health service will ensure that for every citizen there is available whatever medical treatment he requires, in whatever form he requires it, domiciliary or institutional, general, specialist, or consultant, and will ensure also the provision of dental, ophthalmic, and surgical appliances, nursing and midwifery, and rehabilitation after accidents" (para. 426).

The problems that arise in the organization of such a service are not dealt with in the Beveridge report. But, obviously, the implementing of the Beveridge plan, or some modification of it, after the war will entail the organization of a State Medical Service on a grand scale. The present voluntary hospitals will have to become a part of such an organization. Furthermore, even without a Social Security plan which involves a great number of monetary contributions from individuals, economic conditions after the war are likely to be such that it will be impossible to finance large hospitals by voluntary means. It is therefore highly probable that all hospitals will come under some form of State or local council control.

The medical profession welcomes the development of a comprehensive medical service. Measures for the promotion of maximum health in the country by the extension of preventive medicine and the easy availability of treatment are necessary steps in the advance of civilization, and are already overdue. The financing of such a medical service is a social and economic problem and not a medical one. But the *nature of the organization* of a State Medical Service is a matter which vitally concerns doctors in their professional capacity. It is the duty of practising medical men, and particularly the members of the staffs of the voluntary hospitals, to see to it that the socialization of medical services does not result in any loss or curtailment of their *scientific freedom* in the exercise of their profession.

If the planning of a State Medical Service is left in the hands of the politicians and the civil servants it will almost certainly be modelled according to the traditions of the Civil Service and along the lines of the already existing E.M.S. and L.C.C. hospitals. The defects of the Civil Service, particularly in regard to the stifling of initiative and the shunning of responsibility, are notorious (see *Passed to You, Please*, by J. P. W. Mallalieu).

Doctors have, or should have, as their only professional objects the provision of the best possible preventive measures against disease, the best possible administration of treatment, and the most rapid improvements possible in the technique of treatment. They are concerned greatly in the facilities given them for this purpose and demand that they shall be the best procurable, but care little by what machinery these facilities are paid for.

There are in existence at the present time two types of medical service—the autocratic, as typified by the L.C.C. and the E.M.S., and the democratic, as typified by the voluntary hospitals. In the autocratic services full power is in the hands of the chief medical officer; by him it is delegated to the medical superintendents, and by them it is wielded in individual institutions over their subordinate officers. In the democratic institutions full power over medical matters is entrusted to the democratic medical committees, composed of practising physicians and surgeons who are experts in their several lines and who meet and discuss medical matters on a footing of equality.

The Autocratic System

In this system the power over medical matters resides in one man, whether that man be the head of the service or the head of an institution. One man is incapable of having a good knowledge of all branches of medical science, and no human being exists who does not have personal predilections, sympathies, or antipathies, whether these refer to men or to things.

Promotion to the autocratic status goes by seniority and political and administrative acumen. Seniority in an autocratic service is likely to be assisted by a compliant attitude towards superiors, conformity with rules, and conservatism of outlook; it is likely to be impeded by a tendency to criticize and by liveliness or originality of outlook, and even by devoted application to medical practice. The former qualities are good in routine administrators but are fatal to research, for which the latter qualities are essential. Promotion removes the autocrat further from up-to-date medical care of patients and further from the scientific outlook, and brings him nearer to the day-to-day problems of administration and to the political point of view. The autocrat, being immune from the criticism of his juniors, and thus from criticism at all, is in danger of getting to believe that he has a universal knowledge of medicine, surgery, gynaecology, and all the ancillary sciences.

Science in the autocratic system is under several disadvantages. A medical superintendent can forbid the use, in his hospital, of a method of treatment in which he personally does not believe or of which he personally disapproves, however little he may know of the subject in question. This power has in such institutions been not infrequently exercised. Alternatively, should a method of diagnosis or of treatment be disapproved of by the chief medical officer, it can be effectually denied to the practising medical men by withholding the necessary funds. An institution of over 1,000 general beds was considered by the local physician to require an expensive instrument of routine diagnosis. The chief medical officer of the area refused to recommend its provision. When the machine was obtained independently from a voluntary organization, a bureaucratic official storm resulted. In some autocratically run hospital systems a medical officer may not publish a scientific article or paper unless permission has been obtained from his superiors. When it is remembered that the younger men are the initiators of new work, and the older men in such institutions are largely divorced from living medical science, the menace to vigorous scientific development is clear.

Free speech in medical matters is denied to those practising in an autocratic medical organization. A medical officer who criticized his medical superintendent would become unpopular, would jeopardize his future, and would do no good to his patients. Letters by medical officers in the medical papers criticizing the organization or the treatment of their superior colleagues are not seen. Anonymity does not provide an outlook for such criticism, since it is not encouraged by the editors of scientific papers, and rightly, for the principle is wrong. In an attempt to divert criticism certain autocratic institutions have allowed their medical staffs to meet—a generous concession—at regular intervals to discuss internal matters, scientific and otherwise. Such meetings are devoid of power, and have no official status and no power of initiation.

Discipline over the scientific thoughts and actions of medical men can thus be maintained by their more politically powerful senior colleagues by the means mentioned above: threat to promotion, influence of financial control, power over scientific and medical interests, veto of criticism. There is another and more pernicious handle. Should a medical officer be dismissed as a result of a quarrel because he is disgusted with some professional situation, he risks forfeiting part of the sum set aside annually for pension purposes, for the decision rests with his medical superior. This threat grows as years pass; for the sum is greater and his family obligations are increased.

Political pressure is applied with greater ease to the head of an autocratic unit, and this is, of course, the central feature of Nazism and Fascism. Thus in an autocratic system science is more at the mercy of the politicians. This fact constitutes a grave threat to medical research and even to medical education, for politicians have on the whole short-term minds, and are far more interested in the immediate application of available medical methods than in the discovery of newer and better ones. *In medicine the future is always greater than the present.*

A lay member of a certain autocratic committee remarked, "I will not have *my* people taught upon for the benefit of medical students." There is no guarantee that those with such an outlook may not be in a position to dictate to medical science in more ways than one.

In this connexion it is salutary to remember that nearly all advances in science are innovations that are made by persons whose characters are often coloured by outspokenness, independence of outlook, intolerance of mediocrity, dislike of fools, and love of liberalism. They will thus be the natural enemies of the safe man, the careerist, the respecter of forms and precedents, and the efficient administrator of set rules and regulations. History is full of examples proving that new scientific discoveries and advances are often strongly, even bitterly, opposed by the conservative and well-established elders of professions. Opposition is, *a fortiori*, stronger and more ignorant when it comes from the general public, whose point of view is mirrored more or less closely by politicians. In the past, in the absence of an autocratic medical system, this opposition has been stubborn enough. In the presence of such a system it would be hardly less strong. Anaesthesia for women in childbirth was stoutly condemned by certain religious bodies in the past. Lister's innovation of antisepsis met with scorn and obstruction on the part of his elder professional brethren. Pasteur, in his attack upon the theory of spontaneous generation, was bitterly opposed by his academic fellows for many years. Sir James Mackenzie's work, in its earlier years, was scarcely welcomed by the more conservative of his colleagues as it deserved. If these men had been faced with an autocratic power pyramid of senior medical officers and superintendents, it is legitimate to believe that their struggles would have been harder and their success problematical.

The lapse of time does not mitigate the case, for medical problems and ideas are as revolutionary and unexpected now as ever in the past. Nor is it safe to infer that politicians or the public are wiser, or that autocracy will always be benevolent. There is also the risk that the activities of research workers might be forcibly canalized along unprofitable channels to suit the publicity demands of some political campaign. Freedom of scientific action is above all things essential to research, whether this is clinical or laboratory in character.

The Democratic System

Most voluntary hospitals are managed, medically, by committees composed of the members of the medical staff on a footing of complete equality. They elect their own chairman, vice-chairman, and secretary, and these elections are for determinate periods only. They often appoint subcommittees from their members to inquire into and report back upon special points—medical, surgical, pathological, etc. Full medical responsibility is delegated to them by their lay boards. Their advice regarding the medical affairs of their hospitals is respected and nearly always taken by the lay boards. These medical affairs comprise matters of routine, research, equipment, and medical organization, and also the appointment both of house medical officers and of members to the ranks of the consulting staff. The standing and reputation of the great voluntary hospitals of Britain, internationally, in scientific circles, and in the eyes of the public generally, are sufficient proof of the medical adequacy of the system. Free speech, free criticism, free intellectual competition, and professional vigour are safeguarded and encouraged.

Promotion, or standing in the eyes of their colleagues and of the public, is the result of ability, not of seniority. Safe mediocrity, absence of initiative, and a reactionary outlook bring obscurity and not professional success. *Advances in treatment* are the direct responsibility of the individual expert in a particular branch. They cannot be inhibited by ignorant or unsympathetic seniors. *Criticism* thrives in the democratic atmosphere. Any innovation stands or falls by its intrinsic merits.

The lay board has the advantage of direct access to expert opinion in any one of many different branches of knowledge, instead of having to obtain this through an elderly and rather medically rusty autocrat, who may have become a political jack-of-all-trades.

The Two Systems and a State Medical Service

The designers of a State service will be either civil servants or medical politicians. The former are accustomed to ensuring the smooth running of an already existing and scientifically dead function, or a function so static that it bears no comparison with the live sciences of which clinical medicine is composed. Such static functions are the enactment of laws, the supply of transport, electricity, gas, and water, the carrying of the mails, etc. These activities can be efficiently run by autocratic boards. Delegation of responsibility is thus the antithesis of the Civil Service tradition, and the resulting system of control, checks, and counter-checks is the chief reason for the leisurely running and the wastage often seen. The medical politicians, seeking their opportunities as careerists, will not be unwilling to accept a system in which power is centralized *at the top* and *in their hands*, for few men can resist the desire for personal power.

The public must be warned that an autocratic system will impede the speed and the efficiency of medical services, and will be likely to hinder the proper development of medical science, both in the field of prevention and in that of treatment. If the public understands the case, proved already by the voluntary hospitals, neither the lay nor the medical politicians will be likely to obstruct a proper extension of the democratic system.

The public owes to the democratically run hospitals the education of its doctors, first-class treatment of generations of its sick, and research work which has resulted in the saving of millions of lives in the past and should result in the saving of more millions in the future. That these hospitals and their staffs should go cap in hand to the civil servants and the politicians, hoping that on the whole they will not be too severely dealt with or harshly regimented, is a ludicrous situation. They should, if necessary, go direct to the public, by all channels which are available, and should demand freedom to continue to develop democratically in any State service. They should further point out that it is a privilege and a duty of the nation that full and adequate means should be proffered for the furtherance of a freely developing and vigorous medical science. It is, furthermore, a magnificent financial investment.

The democratic system of medical service is entirely compatible with State control. The medical constitution of hospitals should remain as it is at present in the democratic institutions. It would be the privilege of the State to finance these institutions to the necessary extent, and to be represented adequately by financial, legal, or other representation upon the already existing lay boards. In addition a medical organizer should be a member, on an equal footing, of the medical committee, to specialize in and advise upon the minutiae of medical administration in contradistinction to practice.

The medical profession as a whole should also demand that the autocratic type of medical service should be abolished where possible, and should be replaced by a service of the democratic type. What is professionally and scientifically important for the voluntary hospitals is no less important, professionally and scientifically, for their less fortunate State-enslaved fellow institutions.

Conclusion

Hospital staffs should immediately pass resolutions, and, by combining and organizing, should see that these resolutions are implemented in the following senses:

1. No medical system is to be tolerated which is a reversion towards medical autocracy and away from medical democracy.

2. No system is to be tolerated in which free speech on medical matters, free criticism of medical affairs, and free publication of scientific work are discouraged or in the slightest way impeded.

3. The democratic system of hospital organization has proved its value to science, to medical education, and to the public. It is fully compatible, if this last is thought desirable, with State control and State finance of medicine.

4. Combined and comprehensive steps shall be taken, if necessary, by the democratically run hospitals to inform the general public in Parliament or in the Press as to the necessity for freedom for medical science and for a democratic basis for medicine.

TREATMENT OF PHOSPHORUS BURNS

The Ministry of Health has issued the following memorandum (E.M.S.I. 396) on the treatment of phosphorus burns. It should be substituted for the instruction contained in E.M.S./Gen./336 (revised).

At the Incident

1. Apply water immediately to the affected part to extinguish any burning phosphorus and to keep the area moist (water from the water-bottle may be used for this purpose).
2. Apply a clean mines dressing, or clean lint, or clean cloth soaked in water over the burn. Whatever dressing is used it *must* be kept wet, as otherwise it may burst into flame.
3. With the wet dressing in place, the casualty, if a sitting case or able to walk, should be conveyed or directed *at once* to the nearest first-aid post or hospital for further treatment.
4. Stretcher cases must be sent direct to a hospital with the least possible delay. To ensure immediate attention at the hospital these casualties must be labelled, and the label marked with a P. The attention of the ambulance attendant must be drawn to the case.

At the First-aid Post or Hospital

1. Immerse the affected part in water, or, if sufficient water is not available, apply a mines dressing soaked in water. Keep the dressing wet until the following treatment can be applied.
2. Thoroughly flood and wash the affected area with bicarbonate of soda solution (roughly two tablespoonfuls of the powder to a pint of cold tap water). Pick off with forceps any obvious particles of phosphorus, disclosed by examination *in the dark* (phosphorescence).
3. Swab the affected area with a 1% solution of copper sulphate, which will coat any remaining phosphorus particles with a dark deposit of copper phosphide. Remove with forceps or gauze as much of this as is possible without damaging the tissues.
4. Immerse the affected area in the bicarbonate of soda solution for a prolonged period. The duration of this soaking depends upon the size and depth of the burn—i.e., small burns 1/2 hour, large burns 1 to 2 hours. If immersion is impossible keep the sterile dressing repeatedly wetted with the bicarbonate solution.
5. Finally, re-examine the burn in the dark for phosphorescence. If this is not present, dress as for an ordinary burn. If there is still any doubt about the presence of phosphorus, dress the burn four-hourly with lint soaked in sodium bicarbonate solution (2 tablespoonfuls to the pint of water) and retain the patient (if at a first-aid post).

No oils or greasy dressings and no tannic acid, triple dye, or brilliant green must be used in the treatment of phosphorus burns *so long as any trace of phosphorus remains in the tissues.* Oils and greases are solvents of phosphorus, and their use while it is present will cause risk of poisoning from absorption.

Reports of Societies

PROPHYLAXIS OF ACUTE SPECIFIC FEVERS

At a meeting of the Section of Disease in Children of the Royal Society of Medicine on Jan. 22, with Dr. DONALD PATERSON in the chair, the subject of discussion was the prophylaxis of acute specific fevers.

Dr. E. H. R. HARRIES said that the fundamental prophylactic measure was the provision and maintenance of a satisfactory environment, which included not only housing, water supply, and sewage disposal but also attention to nutrition. To this must be added the education of parents and teachers. An important point was postponement of age of attack. The poorer the environment the greater the incidence of measles among children of pre-school age and the higher the proportion of cases complicated by bronchopneumonia. During the 1940-1 measles epidemic in London, thanks to evacuation, the ages of the children admitted to his hospital (North-Eastern) were higher and the mortality greatly reduced. From birth to school age the child's environment was that of its parents; later it became the environment of the school, which might be good, bad, or indifferent from a prophylactic standpoint. Early diagnosis of an acute specific fever might be impossible, or the phenomena might be too vague on a first visit to justify more than a suspicion, and he thought it should be allowable for the practitioner to communicate his suspicion to the medical officer of health, and request removal to hospital for confirmation, without being obliged to make formal notification. During recent years considerable modifications had been made in the matter of isolation. Shortened isolation was made possible in scarlet fever by the use of antitoxin, which was advantageous even in clinically mild cases. After isolation and the return of the child to his community, such measures of disinfection as stripping the paper, etc., were relatively unimportant; ordinary spring cleaning and the open window would suffice. As for contacts, with the aid of the Schick test in diphtheria and the Dick test in scarlet fever it was possible to divide a school community into the safe and the unsafe, and the latter into the susceptible and the dangerous. The safe individuals might be released, although kept under observation, and the unsafe should be immunized. In diphtheria it was desirable to combine passive and active immunization. Duration of passive immunity produced by scarlet fever antitoxin rarely exceeded 10 to 14 days. Active immunization against scarlet fever by multiple skin test doses of toxin was a lengthy and cumbersome process, and duration of active immunity was uncertain.

Dr. A. W. DOWNIE, discussing whooping-cough, said that in active immunization for pertussis the prophylactic vaccines generally used were simple preparations of the dead bacteria. General opinion seemed to be that vaccines were not of much value in the treatment of the disease once the clinical signs had appeared. In one of the first large-scale experiments made in the use of whooping-cough vaccines the vaccine was shown not to protect completely against infection, but the severity of the disease was very much less than in the uninoculated groups, and that had been the general experience. Recently the usual doses of pertussis vaccine were given to a group of children under 3 months of age and to a similar group from 3 to 6 months. There was no harmful effect, and antibody response was satisfactory, though not so good in these younger children as it was at a rather later age. In Denmark vaccine prophylaxis was practised from the age of 1 month. Dr. R. E. SMITH described the abandonment of mass quarantine at Rugby under certain precautions. No quarantine was observed in the case of a number of infections, including measles, rubella, mumps, whooping-cough, scarlet fever, and diphtheria. Of 128 boys who, over a period of seven years, had been in contact with cases, only two had contracted the disease to which they had been exposed, and in no case did any epidemic arise. One important prophylactic measure in individuals susceptible to bronchitis, who might go down with bronchopneumonia if they had measles, was breathing exercises. Another measure was the routine taking of temperatures of those who had been exposed. The greatest of all prophylactics was the fortification of the general health, attention to nutrition, and general environmental well-being.

During some further discussion Dr. A. I. SIMEY said that in scarlet fever immunization they were attacking only the erythrogenic toxin and were taking no account of the organism itself, but it should be realized that the scarlet fever was only one phase of the attack of the scarlet fever organism. Convalescent serum was probably the most valuable form of serum for measles. Dr. W. H. BRADLEY, speaking of tests for vaccines, proprietary and otherwise, said that these were always proceeding. A great deal of assistance would be given to the control of infections if there were closer co-operation—by which he meant intimate daily conversation—between the medical officer of health and the general practitioner, to whom the latest information regarding prophylactic methods was not always made available. Dr. R. A. O'BRIEN said that as long as the policy of decentralization went on co-operative research was made difficult. He hoped that a laboratory and information service would become a prominent feature of the public health service so that people in any one area would be acquainted with what was happening elsewhere.

PLACENTAL POLYPUS

At a recent meeting of the Section of Obstetrics of the Royal Academy of Medicine in Ireland there was a demonstration and discussion of cases of placental polypus.

Dr. BETHEL SOLOMONS showed a specimen of placental polypus in a patient, aged 36, who had had eleven children, the youngest eleven months previously. She was admitted to hospital in Sept., 1942. She had nursed her baby, and menstruation had started again four months earlier; since July bleeding had been more or less continuous. Examination revealed a rather soft, slightly enlarged uterus. The patient was in such a collapsed state on admission that she was given a blood transfusion; as a temporary measure intravenous saline was administered and the uterus plugged. In view of her condition it was decided that conservative measures would be dangerous, and total hysterectomy was performed. The pathological report by Dr. Bourke was as follows: "Tumour—this is a simple placental polypus with necrotic chorionic villi all through it. At one or two places on the surface the villi appear to be covered with living cells. The endometrium in the roughened area above the polypus shows much blood in the interstitial tissue, with large areas of hyaline degeneration around the blood vessels. There is also evidence of early adenomyosis." Dr. Solomons said he believed the condition was very rare; in fact, one of those that he had taught about but had seldom seen; he could find no records of its frequency. The appearance of the specimen was consistent with the description of Novak: he suggested that profuse haemorrhage might occur from rupture of the large venous sinuses at the base of the polypus, and recommended the pathologist to take care to make a differential diagnosis from chorion epithelioma. In this case no history could be obtained of a definite abortion or of retained placenta at the last birth.

Dr. D. J. Cannon showed a case of uterine placental polypus which was associated with bleeding so severe that a transfusion had to be given before operation. He said that curettage revealed a normal endometrium. When the uterus was split after a supravaginal hysterectomy the appearance of the polypus resembled so closely that of a malignant polypus that he decided to remove the cervix and both ovaries. The patient made an uneventful recovery. The polypus showed microscopical evidence of chorionic villi.

The President (Dr. Ninian Falkiner) said he thought a cause of placental polypi was retained placental tissue after confinement. It was fairly common for part of a placenta to remain *in utero* without this being recognized at the time. It might give rise to haemorrhage, and during treatment the placental tissue might be removed. A number of patients went through a period without undue loss and afterwards placental polypi developed. Chorionic tissue became absorbed, but the blood vessels at the base of the cotyledon seemed to remain in the same position. He asked Dr. Solomons how long after delivery his patient had come for treatment. Dr. Cannon had stressed that the condition was diagnosed at operation, but surely diagnosis in these cases should be made not when the abdomen was open but by curettage. It was quite easy as a rule to get a bit of the polypus, and the presence of villi would indicate the diagnosis at once. The pathologist would have no difficulty in stating if the villi were, microscopically, those which were found with chorion epithelioma. Dr. J. F. Cunningham said the reason for the lack of statistics for placental polypus was that it was such a rare condition. He thought he had seen one case 5 months after delivery, and described the symptoms and the treatment he had given for the severe bleeding. He performed a total hysterectomy and gave a blood transfusion. On examination the uterus was empty and there was a large sinus. Dr. J. O. E. Apthorp asked if Dr. Solomons and Dr. Cannon did not think the term "uterine polypus" was wrong and misleading. Both cases showed evidence of actively growing tissue. If a bit of placenta was left behind it was no different from any other foreign body; therefore it was not actively growing. The term should be changed.

In reply Dr. Bethel Solomons pointed out that if there was any doubt as to malignancy, a total hysterectomy should be done. "Polypus" was a better word than "polyp." Curettings might easily be negative, as they were in his case. The last baby was born eleven months previously; the patient lactated for seven months, and then the bleeding started and was nearly continuous. Dr. Cannon stated that his two cases were curetted and both were negative; it was, therefore, very difficult to make a diagnosis by curettage. He performed a supravaginal hysterectomy in the first case and a total in the second. There was, according to Dr. O'Kelly, no evidence of inflammation of the tubes in the second case.

Correspondence

Anaesthesia for Laryngofissure

Sir,—Dr. C. B. Lewis has described (Feb. 6, p. 162) a method of anaesthesia for laryngofissure. He says that the object of this technique is to provide safe anaesthesia for cases of laryngofissure without a tracheotomy and its accompanying disadvantages, and that in eight cases there have been no post-operative chest complications. It is difficult to conceive a more perilous procedure, which runs counter to all the teaching and experience of the late Sir StClair Thomson, and the series of eight cases shows how far it is possible to encroach on the margin of safety which Nature has provided without incurring a disaster. The prejudice against temporary tracheotomy, which isolates the field of operation from the lungs, provides a quiet anaesthesia with no possibility of respiratory obstruction, provides, too, a valuable safeguard in the uncommon but alarming event of post-operative haemorrhage, and is much less likely to cause bronchitis than the insult which Dr. Lewis offers to the trachea, is difficult to understand. It transforms a most dangerous operation into a safe one, and all these advantages Dr. Lewis is prepared to abandon in order to substitute the complicated procedure which he describes. A No. 14 catheter is passed through the larynx without touching the growth, a feat which calls for a dexterity which few laryngologists would claim but must excite their envy. The method of inducing and maintaining anaesthesia is the one most liable to provoke bleeding and thereby both hamper the operation and endanger the life of the patient, and explains why there is afterwards resort to the inflatable cuff which fills the larynx. This is only a modification of Hahn's tube, which was useful in its own day, but was tried, found wanting, and abandoned before the turn of the last century. In any case the control of haemorrhage is no part of the duties of the anaesthetist, but he may be expected to refrain from doing anything to excite it.

However, the least excusable part of the procedure is the administration of morphine or its derivatives both before and after the operation. The patient depends for his continued existence on his ability to cough as soon as the operation is completed, and both by his manipulations and administrations Dr. Lewis seeks to deprive him of this physiological need. This may be novel but it does not sound like progress, and it will be interesting to learn if Dr. Lewis proceeds from eight cases to twenty without reconsidering his methods.—I am, etc.,

London Lionel Colledge.

A Member Resigns

Sir,—Your very definite disclaimer (Jan. 30, p. 135) of any policy against publishing letters which conflict with "high British Medical Association policy" will no doubt clear the ground for a fresh discussion of the future of medical practice in this country. It has seemed strange to me that, at a time when, following Sir William Beveridge's remark in his recent report that it may not appear worth while to preserve private practice, there has been widespread discussion of the implications of that remark and of the implications of the interim report of the Medical Planning Commission, so little of this discussion has appeared in the correspondence columns of the *B.M.J.* As a result of contact with various doctors in this country I am able to testify that the belief that there is such a policy as your correspondent suggested is very widespread. It is a fact that numbers of doctors have refrained from writing to the *Journal* because of that belief; and that may explain the fact that your correspondence columns do not reflect the intense interest in, not to say anxiety about, the future of medical practice.

While you disclaim any considerable censorship of letters, you do not deny what I would consider the most important allegation made in your correspondent's letter—the existence of a "high British Medical Association policy." I think your correspondent was referring to another belief, which is also widely held, that a majority of higher or more central B.M.A. officials are themselves in favour of a planned medical service—"planned" being largely the present-day interpretation of socialized or nationalized medicine—and that such officials are more concerned with putting over their views than in ascertaining and making effective the wishes of the majority of members of the B.M.A. without coercing any dissentient minority. I do not think this suggestion is altogether disposed of by any of the specific answers made in your editorial.

However, proceeding on the assumption that the B.M.A. is a purely representative body, and that it has no vested interests in a profound modification of the organization and functioning of the profession such as is implied in planning, and that its officials are really concerned to discover the views of the members they represent and to give effect to those views, I may, perhaps, be permitted to initiate some further discussion on the future of medical practice by an endeavour briefly to clarify the situation, as I see it.

1. The basic assumption appears to be that the medical profession is not giving satisfaction to the public at the present time. If it were, of course, there would be no need or justification for any alteration. Let us see what this assumption amounts to. In the first place, as things are, a patient goes to a doctor because he is not satisfied with the state of his health. If the cause of this dissatisfaction is one of a large majority of conditions, any doctor will be able to tender the advice or administer the treatment appropriate to the condition. If, however, the condition is beyond the competence of this doctor, he may either refer the patient to a colleague, of whose ability to render the necessary service he is aware, or he may send him to a hospital. This procedure, so far as I am aware, is perfectly acceptable to the patient, but it is not available to everyone, because many patients cannot "afford" to go to a private doctor—that is to say, it is not to the service which they might obtain but to the cost of it that they object. The short approach to this problem is to ask whether the medical profession, as at present organized, is unable to supply a satisfactory service within the limits of present knowledge and technique to any patient to whom expense is no consideration. I think it is undeniable that the answer to this question shows that the cause of such dissatisfaction as exists is simply due to the fact that full medical attention is not available to everyone, because everyone is not in a position to meet the cost of it. It is the availability of medical attention and not the organization of the profession which underlies dissatisfaction.

2. This situation may mean (*a*) that the whole amount of money available for medical services is too little; or (*b*) that there is sufficient money but that it is maldistributed; or (*c*) that there is too much money, and that some of what goes at present to doctors should be diverted to some other purpose, such as paying the costs of administration of a "planned" service, or to creating "funds," or to reducing public indebtedness. An analysis of these questions cannot be undertaken here, but certain facts may be pointed out. One is that an average yearly contribution of £2 10s. per head of the population would provide doctors with an average income of approximately £1,700 per annum, and that the cost of smoking is at least £10 per annum to a moderate smoker. Another is that, despite the other demands of war, enormous sums of money have been spent on increased hospital accommodation. The war has shown that money can be provided at at least 30 times the rate at which it was provided during peace.

3. The proposal which is being pressed forward, from at first sight curiously diverse sources, with extraordinary resources of propaganda, is that to meet the lack of *availability* of medical services, which is due to a lack of money, the *organization* of the profession should be altered. This is just as if there were no organizations conducting car insurance, and because some owners of cars could not meet the cost of repairs the only suggestion put forward was that the Government should take over all motor mechanics and run them from Whitehall, the public, including the mechanics, being taxed to meet the general expense of paying both mechanics and the bureaucrats, and of printing and posting the plethora of forms and returns that seem to be an increasing accompaniment of Government activity.

4. A hierarchical and authoritarian organization of the profession seems to appeal to some members of it and to appal others. Now, whether the dissentients are in a minority, which I very much doubt, or otherwise, it is not very democratic to force them to subjection to a system which they feel stultifies personal initiative and responsibility. If the monetary difficulty of availability were solved first, as it ought to be, the authoritarians could get together and work any system they liked and elect or hire any "bosses" they liked; or else take jobs in the permanent armed Forces or public health departments or other Government-controlled organizations, while the individualists could continue with that private practice which Sir William Beveridge suggests may not be worth preserving, but which those who can afford it seem to prefer. In any case, I think it is incumbent on those advocating drastic change to show that the profession as at present organized is unable to provide full and adequate medical treatment where no question of payment obtrudes before the whole profession is handed over to a legalized system enforced with all the sanctions available to a Government.

To summarize the whole matter: it appears to be the case that a situation of some dissatisfaction arising from monetary difficulties of access to existing medical services is being utilized to create a demand for the "planning" or "socialization" of medicine to the practical exclusion of other methods of dealing with the difficulty. Other methods, which preserve the existing organization of the profession and leave intact personal initiative and responsibility, exist and are in operation in various parts of the world. In that connexion, I think a lead from the *B.M.J.* in publishing or republishing such schemes and possibly organizing small-scale experiments in suitable localities would be valuable before the profession is plunged wholesale into a system of which it has had no experience, which is only tenuously, if at all, related to the situation which causes the difficulty, and from which we would probably be unable to escape if the results were unsatisfactory.—I am, etc.,

London. BRYAN W. MONAHAN.

Dietetics of Pregnancy

SIR,—Mr. R. B. Fisher (Jan. 30, p. 144) purports to quote the conclusions we reached in a paper published in the *Journal* of May 16, 1942 (p. 605). He begins by grossly misquoting us. We found: (1) that in eclampsia the amount of vitamin B_1 excreted in the urine on admission to hospital is significantly lower than in normal pregnancy; and (2) that the concentration of vitamin B_1 in the placenta is also significantly below that of the placenta from normal cases. In our paper we were at particular pains to point out that none of the four other clinical subdivisions of toxaemia (hypertension, oedema, hyperemesis, pre-eclampsia) differed significantly from the normal group (who themselves were excreting abnormally little vitamin B_1). Notwithstanding this careful differentiation, Mr. Fisher refers to our findings as applying to toxaemic patients in general.

Having distorted the careful clinical and statistical differentiation we made between the eclamptic and the other toxaemic groups, he went on to question "the qualifications of your leader writer for the critical appraisal of quantitative data." He himself appears unable to appreciate the qualitative differences that we were at pains to stress. We have established a deficiency of vitamin B_1—to whatever cause it may be due—in the urine and placenta of eclamptic patients, and therefore suggested, as we still believe, that vitamin B_1 might be beneficial to such patients. Mr. Fisher, cloistered as he is in the home of lost causes, would delay any such treatment until all other biochemical abnormalities are identified and can be corrected.—We are, etc.,

W. C. W. NIXON.

London, W 1 E. C. FIELLER.

Phlyctenular Ophthalmia

SIR,—Mr. Arnold Sorsby's careful analysis of this condition, referred to in the annotation in the *Journal* of Sept. 26, 1942 (p. 373), is puzzling to Australians. Phlyctenular ophthalmia was a very common condition years ago, and met with almost entirely in girls who seemed to live largely on tea and bread-and-butter. Anyone now would be hard put to it to find a case. I regarded it as a deficiency disease and treated it with a full diet. Tubercle has greatly diminished, but is still far from absent. It is impossible to disregard the evidence Mr. Sorsby advances, but the facts in Australia are equally cogent.—I am, etc.,

Melbourne. JAMES W. BARRETT.

Weil's Disease

SIR,—With reference to the article by Capt. S. Varadi (Jan. 30, p. 126) I think it of some importance to point out that it is highly probable that more cases of this disease will be diagnosed shortly. In one patient with a mild form of Weil's disease in our hospital recently the diagnosis was proved by the agglutination test performed by Dr. Bedson in Epping Hospital.

The aetiology and epidemiology are well known, also the clinical symptoms, with fever, sleeplessness, stiff facial expression, icteric coloration of skin and sclerotics, somewhat resembling that in acute atrophy of the liver, pains and hypersensitivity of muscles, and irregular action of bowels. It should be noted that the jaundice does not appear immediately after the onset of the disease, but a few days later, sometimes after the temperature has become subfebrile or normal again, as in our case. Prophylaxis is of great importance, as it is known that in the last war an increase in the number of cases was noted (Uhlenhuth and Fromme), though contact infection was doubtless very rare. The saying "Where there are no rats there is no Weil's disease" is well known, but mice could also be responsible for spreading the disease. Water and stores contaminated with the urine of rats are infectious; therefore the fight against rats and mice is the most important point in prophylaxis. Whether ordinary infectious hepatitis in wartime is allied to morbus Weil cannot be proved, but should be borne in mind, and every case of illness with jaundice and high fever should be suspect and the agglutination test should be performed. Only in this way can the disease be diagnosed and cases properly looked after.—I am, etc.,

German Hospital, E 8 K. BLUM.

Spina Bifida

SIR,—In Dr. A. Fry's interesting account of a spina bifida in binovular twins (Jan. 30, p. 131) he refers to the familial incidence of this abnormality, and quotes instances by Butler-Smythe (1889), who reports three cases in the same family, and by Pybus (1921), where four children in a family were affected. The mother of a case I operated upon in 1938, unfortunately unsuccessfully, gave the following remarkable history: 1929, Female child born with spina bifida; lived 30 minutes. 1930, Male child with spina bifida; lived 36 hours. 1932, Male child with spina bifida and cleft palate; lived 3 days. 1933, Normal female child, alive and well. 1934, Male child with spina bifida; lived 7 weeks. 1936, Normal female child, alive and well. 1938, Female child with spina bifida; operated on; lived 2½ months. This is the child to which I referred.—I am, etc.,

London, E.3. J. R. M. WHIGHAM

CO_2 Absorption Technique

SIR,—The subject of CO_2 absorption technique is again brought up in the *Journal* of Jan. 30. Each time a new modification is introduced more elaborate and expensive than the last. I do not doubt the working efficiency of such machines, but from the practical side of administering gas–oxygen–ether certain difficulties invariably arise.

The crux of absorber technique is mentioned by Major J. Montgomerie on p. 130: "The composition of the gas mixture tends to change slowly during the course of the anaesthesia . . . a fine balance is struck between anoxia and the patient becoming 'lighter.'" These remarks, in my experience, are only too true. The absorber method tends to prevent a level plane of anaesthesia, which is important from the patient's point of view and the surgeon's. As Major Montgomerie says: "Owing to the diffusibility of N_2O . . . about 500 c.cm. a minute is required for maintenance." The basal oxygen flow is usually about 250 c.cm. per minute, so that the oxygen : nitrous oxide ratio is not that of surgical anaesthesia.

The well-known advantages of the CO_2 absorber remain with any efficient machine—namely, water-vapour retention and quiet respiration. The saving of gas is, of course, offset by the cost of the machine and soda-lime.—I am, etc.,

London, W 3 E. V. SLAUGHTER.

The Oxford Ether Vaporizer

SIR,—Through the generosity of Lord Nuffield and the kind recommendation of Prof. Macintosh I have had placed at my disposal at the Wellhouse Hospital, Barnet, the Oxford ether vaporizer. During the last few weeks I have anaesthetized patients by means of this apparatus for most of the ordinary operations of surgery (except intrathoracic operations), and have come to some very definite conclusions.

1. It is the first ether apparatus by means of which a really light ether anaesthesia can easily be administered.
2. There is no difficulty in giving a deep ether anaesthetic and obtaining perfect relaxation.
3. However deep or however light the anaesthetic, the patient always gets enough air and always remains a good colour.
4. Very small quantities of ether are used and there is no waste ether to make the atmosphere of the theatre unpleasant.
5. The constant unvarying percentage of ether given off at any given setting of the indicator presents great advantages.
6. Endotracheal or any type of inhalation anaesthesia can be administered.
7. Most important of all, the use of the machine is readily acquired by students after most brief instruction, and the unpractised anaesthetist can, with very little experience indeed, give a satisfactory anaesthetic.
8. The Oxford vaporizer appears to be the safest way of giving ether.

After twenty years as a general practitioner anaesthetist I can speak with some authority on anaesthesia in general practice, and I consider the Oxford vaporizer the apparatus of choice for the general practitioner anaesthetist. I note with some regret that this machine is not yet in use in many teaching hospitals, and I hope that no time will be lost in introducing it into all hospitals where students are taught or where the occasional anaesthetist has to practise. The expert professional anaesthetist can obtain excellent results by many techniques and from the use of many agents, but between him and the general practitioner anaesthetist, however gifted the latter may be, there is a great gulf fixed. This gulf can in nowise be crossed, and it would be very much in the public interest if this truth were to be understood and admitted, and if many of the newer methods of anaesthesia were to be confined exclusively to the full-time professional. The Oxford vaporizer, however, offers to the general practitioner an extremely safe and simple way of giving anaesthetics on those many occasions when he is called upon to do so.—I am, etc.,

New Barnet. JOHN ELAM.

Diphtheria during Immunization

SIR,—May I, as one concerned with diphtheria cases in hospital, comment on the medical memorandum under the above title submitted by Dr. G. A. Garrett (Jan. 23, p. 102).

The event recorded is not unusual; many similar cases could be cited from fever hospital records for the last year or two, and it is easy to see why. When prophylactic injections are given to large numbers of non-immune persons in a community wherein diphtheria is still endemic, the conjunction of the two events—viz., an injection and an attack of diphtheria—in the same person must inevitably occur sooner or later; it is particularly likely to occur if immunization is postponed until just after a child's first entry to school. The diphtheria may appear soon after the prophylactic injection, but it may equally well precede the date proposed for an injection. Of course, in the former order the double event is well remembered; in the latter, it is quickly forgotten.

A mild diphtheria, therefore, need not be styled a "phenomenon" merely because it occurs soon after a prophylactic injection, and it is equally unnecessary to postulate any causal connexion between one and the other. I firmly oppose the suggestion that the taking of "swabs" from healthy throats (or noses) should be a preliminary to immunization. The swabbing of healthy persons is rarely justifiable; certainly, the occurrence of "diphtheria during immunization" furnishes no indication for the practice; far from being "a valuable procedure," it would be utterly useless.

As for the recommendation to "administer antitoxin," I am not aware of any evidence to show that diphtheria antitoxin is of any help in ridding diphtheria carriers of their germs, and, presumably, antitoxin given shortly before the prophylactic substance would nullify the antigenic property of the latter and defeat the end in view. Let children be immunized at the proper time—namely, on completion of their first year—then we shall not hear much about "diphtheria during immunization."—I am, etc.,

Cottingham, E. Yorks. NIGEL W. ROBERTS.

SIR,—The lay press has quoted freely from Dr. G. A. Garrett's medical memorandum on diphtheria during immunization (Jan. 23, p. 102). This method, as one paper says, "of providing opponents of immunization with an unexpected argument in their favour" undoubtedly calls for more careful choice of articles for publication in the *B.M.J.* Was there any adequate justification for publishing such an article when there is a perfectly logical and simple explanation for the onset of non-clinical diphtheria (I should really diagnose the case described as tonsillitis) after one dose of A.P.T.?

The following facts appear worth recording in view of the wide publicity afforded Dr. Garrett's untimely communication.

1. It is now recognized that one dose of 0.2 c.cm. A.P.T. does not immunize a child against diphtheria.
2. One dose of 0.2 c.cm. A.P.T. has no influence or effect on a carrier of K.L.B.
3. Dr. Garrett does not state whether there was any contact or possible contact with diphtheria between the time of injection and the onset of symptoms of tonsillitis.
4. He does not state whether the child had been Schick-tested or swabbed before the single injection.
5. The symptoms (of tonsillitis) cleared up with the treatment for tonsillitis.
6. No information is given as to whether virulence tests were carried out.
7. No information is given about further swabs—i.e., to check up on the first (which might have been an error) and to establish whether the child was a carrier.
8. Finally, many of us have seen cases where all signs and symptoms have cleared up without antitoxin and the children were quite well by the time a positive swab was returned.

I have no doubt Dr. Garrett was well meaning in his communication and probably never foresaw what must now be to him most unwelcome publicity.—I am, etc.,

Ramsey, Isle of Man DANIEL ROBERTSON.

Pernicious Anaemia of Pregnancy

SIR,—In your excellent leading article on the above (Jan. 23, p. 105) you fail to find convincing evidence that whole liver by mouth is sometimes more effective in treatment than parenteral extracts. It was perhaps not made sufficiently clear in the study of 23 Newcastle cases which I made with Dr. T. C. Studdert (*Lancet*, 1942, **2**, 332) that five cases which responded to raw liver had already failed to show any significant response to normal diet plus marmite and refined and crude liver extracts. This finding was indeed our chief reason for publishing the series, and has since been confirmed in other cases by personal communications from other workers in this field.

It is unlikely that this response can be due to the amount of iron contained in the raw liver, and it would appear to be due to some additional haemopoietic factor. The same effect of whole liver is very occasionally seen in cases of otherwise typical true pernicious anaemia resistant to parenteral extracts.—I am, etc.,

H. G. MILLER,
Flight Lieutenant, R.A.F.V.R.

Military Psychiatry

SIR,—Dr. Richard Eager (Jan. 23, p. 111) writes, "My contention is that if more serious attention were given to nervous and mental manifestations before enlistment and more cases presenting these symptoms were rejected instead of being suspected of being malingerers, a great deal of time, trouble, and expense would be saved." I have had experience on a medical board during the first three years of its existence. A board of a chairman and three members has to examine 30 recruits in three hours, but this time is often exceeded. This does not give time for a lengthy inquiry into a man's mental condition, still less to solve the difficult problem of how he will react to the entirely different surroundings in the Services. Contrast this with the conditions in which the military psychiatrist works. The recruit has had weeks and often months in the ranks when he is under military and medical observation before he comes before the psychiatrist. This most important information is provided for the latter, but medical boards have to do without it. Even with this great advantage, does the psychiatrist decide the recruit's fitness at the end of, say, ten minutes, or does he keep him under observation for a few days?

Some neurotic cases are manufactured by the Services. In the last war I had charge of a number of semi-convalescents, among whom was a lad of about 20. The Army had sent him into hospital, obviously to get rid of him. He had been in other wards before reaching the semi-convalescents. Inquiry showed that he had been scolded and treated as an outcast in the other wards. Information of his treatment in the Army was lacking; asking the lad was obviously unwise. His history was that he was cantankerous, disobedient, and lazy. When I saw him he was dejected, sullen, and perverse. He was put in a section in charge of a V.A.D. of exceptional ability. She treated him as a human being, and soon transformed him into a bright cheerful lad willing to do any work which came along. His condition was clearly due to the badgering and bullying he had had. What subsequently became of him I do not know, as I was moved elsewhere. In the same war I was called to a Royal Naval establishment to see a sea-scout (employed as a messenger), aged about 16, reported "to have gone off his head." He was in a state of hysteria, severe enough to give colour to the non-medical diagnosis. I knew him and his family to be intelligent and free from any nervous instability. I diagnosed correctly that his condition was due to bullying by a naval officer. Had this bullying continued, the lad would have become a nervous wreck. The position was explained to the naval officer and the lad had no recurrence.

One hears that there is no harsh treatment in the Services now. One has had only to be where training is going on to know that this is not the universal rule. Discrimination is often wanting; some men do not understand anything but harsh treatment, but it is fatal for others. A sensitive lad who has led a sheltered life—some are very sheltered now—though perfectly fit at his medical examination, when pitchforked into the rough and tumble of the Services readily develops a neurosis unless carefully handled. Further, if a man wants to get out of the Service nowadays he has only to be sufficiently troublesome to get his discharge, and the medical board is blamed for passing him.

Nocturnal enuresis is a difficulty. There is no physical sign, and even if the recruit brought his wet bed with him it would not be proof of genuine enuresis. If a medical board began asking every recruit whether he wetted his bed it would not be long before every shirker came with that story. Reliance cannot be placed on parents' statements. In one instance a mother wrote to a medical board saying her son, due for examination, was a bed-wetter and asking that he should not be told. The son, however, stoutly denied the statement.

A problem which confronts a medical board occasionally is this. A man tries to get exemption as a conscientious objector and fails. He is determined not to go into the Service. At his medical board he is obstructive. Examination shows he is fit. (This is not an imaginary case.) Is the medical board to pass him fit when it is obvious he will make himself such a nuisance that he will be discharged from the Service, or to pass him as unfit and let him rejoice while other men fight for him and be an example of how to "work it" to other shirkers? It is likely that a few unsuitable cases are passed in fit, but to expect medical boards to exclude every recruit who may break down under Service conditions is to demand the impossible.—I am, etc.,

E. P. DICKIN.

Thread for Sutures in Tonsillectomy

SIR,—In the *Archives of Otolaryngology* for November, 1942, A. J. Podboy recommends the use of thread for sutures in tonsillectomy. I have been using this material in my tonsillectomy cases for the past two years, and I find that it has no disadvantages and is in fact easier to handle than catgut. It is readily sterilized by boiling for twenty minutes. A tube of catgut costs 1s. 6d. and provides material for four or five ligatures. A reel of thread costs 1s. and will make about 300 ligatures. General use of this suture material in tonsillectomies would result in great economy.—I am, etc.,

Torquay W. H. BRADBEER.

Radiological Diagnosis of Disproportion

SIR,—May I endorse all that Prof. J. Chassar Moir said in the discussion on the above subject at the meeting of the Section of Obstetrics and Gynaecology of the Royal Society of Medicine (Jan. 30, p. 142). It is now eight years since my original paper on cephalometry was read at the Royal Society of Medicine in March, 1935, and in that time most of the points made have passed from ridicule almost to the blessing of respectability. There are still two points, however, which in my view do not receive enough attention.

1. *The Plastic Head.*—Any foetal head with a biparietal diameter of 3.7 inches or less will be plastic and will mould easily and safely to conform to moderate degrees of contraction, whereas a head with a diameter of over 3.75 inches may be very rigid. There is positively no clinical means of recognizing this point at which certainty of safe delivery changes to dangerous uncertainty. Nothing has altered my conviction that induction of labour by rupture of membranes should be performed when the biparietal diameter reaches this point (3.65 inches) (*a*) in all cases of moderate contraction of inlet or outlet and (*b*) in breech cases when attempts at version have failed. This measurement will ensure (1) a plastic head; (2) a body which is not unduly large; (3) a baby which can be easily and safely reared.

2. *The Interischial Diameter.*—This measurement, between the tips of the ischial spines, shows at once if there be any contraction of the outlet. It is easily made with sufficient accuracy directly from a film taken for pelvimetry in the standard sitting position. With a focus-film distance of 30 inches, a deduction of half an inch should be made for correction of magnification. This measurement in a normal pelvis is about 4.5 inches, and anything below 4 inches gives warning of serious difficulties ahead, and full consideration should be given to this point when deciding in favour of Caesarean section or induction. All the necessary information can be obtained from two films by the technique described by me, whether the head be in the pelvis or in the fundus.—I am, etc.,

Totnes, Devon. NORMAN REECE.

Stilboestrol for Immature Infants

SIR,—Drs. W. R. F. Collis and M. A. Majekodunmi (Jan. 9, p. 31) recommend thyroid in the treatment of premature infants. About 2½ years ago I started using stilboestrol instead of thyroid and found that it maintained the body temperature quite as well as thyroid but had a much greater effect in stimulating growth. I have had few opportunities of using it on premature infants, but the results were so encouraging that I started giving it to full-time immature infants. The results were immediate, a gain of 6 oz. a week being often obtained where the previous rate had been 1 or 2 oz. a week.

The usual dose I used was 1/6 mg. once or twice daily, kept up for 2 or 3 weeks until the gain had been well established. No ill effects were seen except in one case, a mongol of about 3 months, where the weight had been stationary for some weeks. There was a gain of 8 oz. the first week, but after that the infant vomited with even the smallest dose.—I am, etc.,

London, W 14 F. N. HOLDEN

Treatment of Small-pox

SIR,—I was particularly interested in Dr. J. T. Neech's letter (Jan. 23, p. 113) regarding the above as in 1882 I had a severe attack of varicella and my father "painted" the worst of the spots, which gave me relief from itching. Years later he told me it was pure carbolic acid, and this we used successfully in an isolated case of modified small-pox 20 years afterwards. He had been told of this when house-surgeon to Prof. Spence in Edinburgh.—I am, etc.,

Hatfield. ARTHUR F. PERIGAL.

X-ray Apparatus at Health Centres

SIR,—We ought to determine what will be the function, size, and location of the health centres before we discuss whether *x*-ray apparatus ought to be located in them. Taking a realistic view of the matter, I believe that the present doctors' surgeries will be gradually transformed into health centres. About 5 or 6 such centres will be sufficient for a town of 50,000 persons. The centres will be placed in various parts of the town, so that the doctors may be near the homes of their patients.

I believe it would be disastrous to set up *x*-ray apparatus in these "district health centres." But in larger towns and cities it is probable that a central health diagnostic clinic or centre will be required. This central clinic will develop out of, and perhaps in relation to, existing hospital out-patient departments. Every branch of hygiene, medicine, and surgery will be represented on its specialist staff. It is in the central clinic and not in the peripheral health centres that mass radiography and all other forms of radiography should be carried out. If, however, no such central clinics are established, then it will be essential to place an *x*-ray apparatus and a radiographer in one or other of the primary health centres in every considerable town or country area.—I am, etc.,

Worcester HOWARD E. COLLIER.

Private Fees of Salaried Medical Officers

SIR,—Much attention is now being directed to the conditions of medical practice after the war. I venture, therefore, to raise a point which affects the conditions of employment of medical practitioners working in hospitals for a whole-time salary. It is the practice in hospitals administered by certain authorities that all fees paid to their whole-time salaried medical officers for incidental services are surrendered to the hospital authority. The services in question are the writing of reports for insurance companies or legal firms, the attendance at coroners' or other courts, and the signing of cremation certificates.

There are, however, other hospital authorities who lay no claim to these fees on the ground that they are fees paid to the medical practitioner as a reward for services which lie outside the scope of his routine medical duties, and which are frequently performed in his spare time. I believe that this latter attitude is the correct approach to the problem, and that it is a bad principle for a hospital authority to adopt the attitude that no man on a whole-time salary must in any circumstances take a fee, even though he has had to take on work outside that for which he receives his salary. In this belief I seem to be supported by the Ministry of Health, who apparently permits its whole-time E.M.S. officers who are examiners to the Conjoint Board and other examining bodies to retain their examining fees.

It is possible that this contention would be shared by a majority of the medical profession, and if put forward persuasively by the B.M.A. would be conceded by those hospital authorities who at present take the opposite view. If conceded, it would benefit principally the lower-salaried junior medical officers, who, in my opinion, have always done the bulk of the work in any hospital service, and who will probably continue to do so, even after the war.—I am, etc.,

London, S E 1 T. W. MIMPRISS.

"Calorie Control" Diabetic Diet

SIR,—The juxtaposition of Dr. A. C. Crooke's and my letters (Jan. 30, p. 143) emphasizes the complete divergence of our beliefs on the above subject. He answers some of my questions, avoids others, and asks some in return, so perhaps you will permit a reply, final so far as I am concerned.

I studied Prof. Ellis's article in 1934 which described temporary improvement in a few diabetics fed on 400 to 600 g glucose with *hourly* insulin injections, the timing of the latter I am sure producing the improvement. When this was stopped complete relapse ensued, and I can see no relevance between this experiment and the practical daily problems of diet and insulin, and would be surprised if Prof. Ellis sponsors his experiments as supporting the principle of the new diet. Does he?

We disagree fundamentally on the effect of C. or bacon and egg (I like both) for breakfast. Insulin lowers blood sugar; C. raises it and balances insulin action; protein and fat have no such action for hours, if at all. I and my patients would have (and some have had) intense hypoglycaemia if, omitting toast or porridge, we substituted equicalorie bacon and egg (pre-war). Dr. Crooke states that this does not happen to his patients, but publishes no detail to prove it, and I could certainly convince him should he agree to experiment on me or my patients. It appears I must challenge him, and I do, to give himself 20 to 30 units of insulin and to compare the effect of combating the resultant hypoglycaemia with bacon and eggs or sugar, porridge, or bread. I must conclude that, when his patients escape hypoglycaemia on omitting carbohydrate, they must be running such high blood sugars that this buffers the insulin when no C. is eaten—a common enough state in many patients, my own included.

It is no argument for the new diet to claim that 528 patients have done well on it, because, having no scales, they could not apply the dangerous principle to which I object. The cases I have seen supposedly on the diet were not, as Dr. Crooke suggests, long-standing confirmed high P. & F. addicts, but new cases. Furthermore, he contrasts the welfare of his patients on the typical new diet (260 C., 70 P., 80 F.) and the old (230 C., 90 P., 80 F.), both roughly 2,000 calories, and in these there is no practical difference. I cannot see any real change from the diets commonly used by the late Dr. Leyton at the London.

Dr. Crooke asks if I provide scales for my patients to weigh my diets—a sting in this! Unless I can, or know the patient has a scale, I never prescribe a weighed diet and consequently have for two years treated new patients almost entirely on my simple "unweighed" diet and bread measure, published by Messrs. H. K. Lewis and Co. in 1931. It takes no heed of calories, but regulates the C. to balance the insulin accurately enough, and, if Dr. Crooke does not know it, I shall gladly send him a copy.

I regret in some ways our public controversy, as it can interest only a few, may confuse many, and obscures the common interest Dr. Crooke and I have in running useful clinics for the benefit of diabetics. But I think the basal principle of his diet untrue and dangerous, and can ascribe the absence of hypoglycaemic disasters only to the fact that it has not been applied in practice by his patients.

If Dr. Crooke is unconvinced, let us have facts and arguments before experts, such as the "Carbohydrate Club," which exists and meets in London. If I am proved wrong, I am not too old to change my views, eat my diet cards, and start afresh, after public acknowledgment of my errors. I expect the same from him.—I am, etc.,

London, W.1. R. D. LAWRENCE.

Adoption of Children

SIR,—Among many other social workers we should like to endorse the views expressed in the letter from the chairman of the National Council for the Unmarried Mother and her Child (Jan. 23, p. 115) emphasizing the supreme importance of safeguarding the interests of unwanted children when arranging for their adoption, and to deprecate action being taken except through approved adoption societies. Fortunately, the Government's recent decision to put into force the Adoption of Children (Regulation) Act will go far in reducing the dangers referred to in Mrs. Fisher's letter.

We understand that the inclusion of personnel of Citizens' Advice Bureaux in the list of those who, without training and experience, have arranged adoptions is based on the action of one worker in one bureau, out of a total number of over 10,000 voluntary workers working in more than 1,000 bureaux. There is therefore no evidence, so far as these bureaux are concerned, to show that inquiries dealing with this subject are not passed on to be dealt with by experts, in accordance with one of the guiding principles of the service.—I am, etc.,

R. C. NORMAN,
Chairman, C.A.B. Central Committee,
Feb 6. National Council of Social Service.

Freedom and the Beveridge Report

SIR,—Dr. E. U. MacWilliam's remarks (Feb. 13, p. 200) with regard to Divisional meetings of the B.M.A. are timely, and the example given by him of a general statement of policy presented to one Divisional meeting for consideration is one with which, I feel sure, the majority of members of the B.M.A., both at home and in the Services, would be in entire agreement.

The main issue, at the present time, is whether we, as medical men, can prevail against outside pressure, and maintain our individual freedom and the liberty of the profession. It is up to all B.M.A. members to attend the meetings of their Divisions, and to make it perfectly clear to their representatives that they mean to place the freedom of doctors as individuals in the forefront of B.M.A. policy—and that these representatives have no mandate whatever for compromise on the lines of the motion printed in the *Supplement* of Feb. 13 (p. 25). To make the freedom of action of the profession dependent on whether the Government passes the Beveridge scheme *in toto* or not is monstrous. It is absolutely untrue to suggest, as some do, that a centrally controlled medical service is necessary to provide for the needs of the community. What appears to be true is that the medical profession, being independent, is looked upon with disfavour by those who are intent on liquidating free British institutions.

May we not look to the B.M.A. to uphold the freedom of medical men at this critical time?—I am, etc.,

London, N.W. BASIL L. STEELE.

Obituary

F. H. EDGEWORTH, D.Sc., M.D.

Emeritus Professor of Medicine, Bristol University

In the death of Emeritus Prof. F. H. Edgeworth, Bristol loses one of its most distinguished sons. His father was Dr. T. F. Edgeworth. Francis Henry Edgeworth was educated at Clifton College and Caius College, Cambridge. He secured a first in the Natural Sciences Tripos, and was Shuttleworth Scholar of Caius. He subsequently entered the Bristol Medical School and took his M.B., B.Ch.Cambridge in 1889. He also studied in Paris, Gottingen, London, and Dublin, taking the D.Sc.Lond. in 1903 and his M.D.Cantab. in 1908. Edgeworth was appointed assistant physician to the Bristol Royal Infirmary in 1893 and physician in 1906, holding this latter appointment until 1924, when he became an honorary consulting physician. In 1905 he was appointed professor of medicine in University College, Bristol, and later occupied the chair of medicine in the university. He was both an accomplished physician and an eminent research worker. In his clinical work he was particularly successful in the difficult art of differential diagnosis, especially in relation to diseases of the central nervous system. He was much beloved by his patients, whom he always treated with great kindness. It was a matter of supreme indifference to him whether a patient had arrived at the Royal Infirmary clothed in rags or was seen by him at his private residence arrayed in fine linen. Edgeworth was the author of numerous monographs on medicine and science, but his *magnum opus* was a volume on *The Cranial Muscles of Vertebrates*, published in 1935 by the Cambridge University Press. This book required a great deal of work, which he carried out with meticulous care.

In his relations with his fellow men he always adopted that line of conduct which appeared right to him, irrespective of whether it was to his own advantage or otherwise. He was devoted to his wife, whom he married in 1896. She became an invalid shortly after their marriage, and predeceased him in 1931. His affection for her is revealed in the words of the dedication of his great work to her: "*In memoriam uxoris meae quae mihi, ut in ceteris rebus, ita in hoc opere et socia erat et adiutrix.*" After his wife's death Edgeworth went to live at Bath, and during the "blitz" of last April was buried for some time under the ruins of his house. He bore this calamity with his usual fortitude, and referred to it as "just an incident." His death occurred at a nursing home in Bath following an operation. He leaves an only son.

O. C. M. D.

SIR STCLAIR THOMSON

Prof. GREY TURNER writes: The death of StClair Thomson leaves the profession bereft of a great personality. Of his contributions to the special branch of surgery to which he devoted himself I am not prepared to write. It was a devotion to medical history and especially the Listerian era that furnished a mutual bond. His presidential address to the Medical Society of London in 1917 dealt most delightfully with the life of its founder, John Coakley Lettsom, and was a very model of what such addresses should be. I have reread it several times and always with renewed enjoyment. But it was his association with Lord Lister, as his last house-surgeon at King's, that enabled him to speak with such great and sympathetic authority on everything that concerned that dear man. Thomson's address on his great master delivered at the Royal Society of Medicine on April 4, 1927, during the Lister Centenary celebrations, was a really wonderful occasion. It was universally applauded as an outstanding success, and I always felt that it should be read by every student of medicine. Sir StClair did provide a thousand reprints to be stored at King's so that for years to come every new student might be presented with a copy. As recently as March of last year he gave an admirable address on Lister before the students of the Medical Faculty of the University of Edinburgh. Writing to me about that time he expressed his joy because he had discovered that by standing on tiptoe looking out of his bedroom window at the Caledonian Hotel at the end of Princes Street he was just able to see the house where Lister lived during his first Edinburgh period. Thomson was a great host, and what a delight it was to be a guest at his hospitable home in Wimpole Street! In almost his last letter he expressed regret that enemy action had driven him from London, for, as he said, "I am now an exile and a wanderer. I had looked forward to ending my days with all my books and toys around me, but there is little prospect of having a home again." The example of his advancing years was itself a great lesson, for when the handicap of deafness cut him off from the drama which he loved so well, he found compensatory interests. One of these was the ballet, though those of us who knew him best recognized that this was really a return to an old love.

PERCIVAL JOHN HAY, M.D.

Consulting Ophthalmic Surgeon, Royal Hospital, Sheffield

We announce with regret the death on Jan. 17 of Dr. P. J. Hay of Sheffield. Percival John Hay received his medical education at Edinburgh University, qualifying M.B., Ch.B. in 1901, and taking his M.D., for which he was highly commended, in 1904. He early specialized in ophthalmology, among his first appointments being that of resident surgical officer, Birmingham and Midland Eye Hospital. For a period he was ophthalmic specialist, Cambridge Hospital, Aldershot. At the time of his death he was ophthalmic surgeon to the Education Committee and the King Edward VII Hospital, Sheffield, and consulting ophthalmic surgeon, Royal Hospital, Sheffield. Dr. Hay had been a member of the B.M.A. since 1904, except for a brief period during the last war, and had been a member of the Ophthalmic Group Committee since 1929. He was honorary secretary of the Section of Ophthalmology when the Association met at Glasgow in 1922, and at the Belfast Meeting in 1937 he acted as vice-president of the same section. He was chairman of the Sheffield Division in 1936-7 and represented his constituency at the Annual Meeting at Oxford in 1936.

Among his contributions to the literature on the eye and its diseases was the Middlemore Lecture in 1929 on "Astigmatism." At the funeral, which took place at Sheffield on Jan. 21, the B.M.A. was represented by Dr. A. B. Nutt. A colleague sends the following appreciation:

The medical profession of Sheffield has suffered a great loss in the death of Percival John Hay, which has added yet another name to the list of casualties of medical men on the Home Front, for his untiring devotion to duty was directly responsible for his death. Hay was not a native of Sheffield, coming to the city just before the last war and joining the staff of the Royal Hospital in 1916, but he soon established himself in the esteem of his colleagues, who recognized in him a man of great charm, though reserved and retiring in character. He threw himself whole-heartedly into the work of the ophthalmic department of the hospital, and within a few years had built up a reputation extending far beyond the Sheffield area. His influence was felt not only in his own department; his advice and opinion, always sound and freely given, were often sought by his colleagues in matters of general administration of the medical and surgical sides of the hospital.

As an ophthalmic surgeon he was recognized as being in the first rank, and his enthusiasm was such that after the foundation of the North of England Ophthalmological Society, for which he was responsible, the meetings of that body proved so interesting that not only were they well attended by members but they attracted visitors from the ranks of general medicine and surgery. His interest in this ophthalmic child of his never waned. Year by year, whenever possible, he organized foreign tours which were recognized as invaluable educational enterprises as well as delightful social events. Though many men would have relinquished the hard work inseparable from such an arduous task as falls to the lot of the secretary of an active society he conscientiously did his full share and was still secretary at the time of his death. From 1940 to 1942 he was Master of the Oxford Ophthalmological Congress, and in 1942 was elected to the highest honour in his own branch of the profession—that of president of the Ophthalmological Society of the United Kingdom.

His death will leave a real gap in the life of the Voluntary Staff Club of Sheffield, to the founding of which he contributed not a little, being its first secretary, and he will be genuinely missed by all who knew him. He leaves an only daughter, having lost his wife early in their married life.

PRESTON KING, M.D.

The death on Jan. 29 of Dr. Preston King has removed a notable figure from Bath medical circles. Preston King received his medical education at Cambridge and St. Thomas's, qualifying M.R.C.S. and L.S.A. in 1887 and taking his M.B., B.Ch. the following year; he proceeded to the M.D. in 1891. He went to the Royal Mineral Water Hospital, Bath, in 1890 as resident medical officer, and three years later set up in practice in Gay Street. Three years later again he was appointed honorary physician to the hospital, a post which he held until 1912. He practised chiefly as a spa physician and published a book on *Bath Waters*. He was also on the staff of the Royal United Hospital as assistant physician, relinquishing that appointment in 1905 to become the institution's first radiologist with the title of "physician-in-charge of the electrical department." In 1901 he joined the City Council, was elected Mayor in 1914 and again in 1917, and Alderman in 1918.

Preston King was a pioneer in other things besides radiography. He was the first medical man in Bath to possess a self-propelled vehicle. This was an early type of steam-driven car, the passage of which up Gay Street in 1901 often meant that the thoroughfare was shrouded in fog for several minutes. Unfortunately, it blew up one day on the way to Wells, and was soon replaced by a petrol-driven car, which proved much more satisfactory and lasted many years. He was also one of the first to be initiated into the mysteries of cinematography by his friend Rudge, who was its inventor in the early part of the century. Preston King was a strong advocate of euthanasia for hopeless cases, and of vivisection of criminals condemned to death, their consent being first obtained and the death sentence commuted if the experiment itself did not prove fatal. He did not hesitate to advance these views publicly, gaining a fair measure of support but also coming in for very spirited adverse criticism. "P. K.," as he was known, was one of the kindliest of men. He had a whimsical wit, and any meeting, medical or lay, knew it was going to enjoy itself as soon as he rose to his feet. He is survived by his widow: their only son died some years ago.

HOWARD KELLY, M.D., LL.D.

Prof. GREY TURNER writes: The death of Howard Kelly of Baltimore at the ripe age of 85 recalls the early days of the Johns Hopkins Hospital, for Kelly was one of the four original heads of divisions and figures in the famous Sargent portrait of that notable staff together with his colleagues Osler, Halsted, and Welch. The picture now hangs in the Welch Memorial Library in Baltimore. But though he was only a very young man when appointed to the Chair of Gynaecology, he had already done notable work, which was perpetuated in his magnificent two-volume *Operative Gynecology* published in 1898, with those wonderful illustrations by Max Brodel which have never been surpassed. But he was not limited by any narrow devotion to his own subject, and his introduction of the simple cystoscope which bears his name opened up a large field of activity in genito-urinary work. Here again he made notable contributions, and in the days before *x*-ray examination became so reliable the use of the wax-tipped catheter for the detection of ureteral calculi was a very useful method which he developed. It ought also to be remembered that he endeavoured to extend the use of his form of cystoscope to the male and published a paper on the subject as long ago as 1898. His modification of the Mayo operation for umbilical hernia, the short rectal speculum, and "Kelly's rake" each shows his wide interest and activities. His volumes on gynaecology were followed by the large book, *Appendicitis*, published in 1905, for which he was also responsible in collaboration with Hurdon; the beauty of the illustrations in that work caused quite a sensation at the time. He was a most skilful operator, and I can never forget the impression he made when in 1905 he operated in the old Royal Infirmary in Newcastle-upon-Tyne at the invitation of Mr. Rutherford Morison. The patient was suffering from a septic pelvis with a temperature chart "like the peaks of the Himalayas," as Kelly described it. He cleared out the pelvis beautifully and it was altogether a most masterly performance, but I think, if anything, it was almost surpassed by the exhibition of cystoscopy by his own method with which it was followed. He invited us to time him in passing the ureteric catheter, but before we could get out our watches the instrument was safely introduced up to the kidney pelvis. On the same occasion I cherish the recollection of quite a long visit which he paid to the pathological museum at the College of Medicine. I was assistant curator at the time, and the interest he took in the specimens that I was able to show him was a great encouragement. I never saw a larger audience of medical men in Newcastle than on the occasion when Kelly was billed to lecture under the title of "Lest we Forget." There was great speculation as to what he intended to talk about, and I somehow feel that the audience would not have been quite so large if it had been known that he was going to lecture on Walter Reed and his work in connexion with banishing yellow fever from the Panama Canal zone. From about the time of the last war Kelly's name rather seemed to disappear from professional activity, although it was often hinted that he was carrying on important work in the use of radium. His views on evangelical work, temperance, and social welfare often brought his name before the public, but the methods he employed in promulgating his views on these subjects at all times occasionally caused a little discomfort to his friends notwithstanding his obvious sincerity.

JOHN KEAY, C.B.E., M.D., F.R.C.P.Ed.

Dr. John Keay, who died at his home in Beaminster, Dorsetshire, on Jan. 21, aged 83, was born in Co. Wicklow. He began his medical studies at Owen's College, Manchester, but soon afterwards transferred to Glasgow University, where he qualified M.B., C.M. in 1881. He was successively house-surgeon and house-physician at the Glasgow Royal Infirmary, and then took a course of postgraduate study in Vienna. Returning to Scotland he began his life's work in psychiatry by taking a junior assistantship in Crichton Royal, Dumfries, in the spring of 1883, subsequently holding senior appointments at Polton and Inverness. In 1904 he became medical superintendent of Bangour Institution, near Edinburgh, which post he held until he retired in 1931. He was also lecturer on mental diseases at the School of Medicine of the Royal Colleges. He thus rendered almost half a century of service in Scottish lunacy administration. In 1881 he proceeded M.D.Glasgow with a thesis on "Some Features of Modern Asylum Practice," and two years later was admitted a member of the Royal College of Physicians of Edinburgh, being elected to a Fellowship in 1892. As president of the Caledonian Medical Society in 1908 he gave an address on "Fifty Years of Scottish Lunacy Administration," summarizing the evolution of lunacy law and asylum practice from 1855 onwards. On the outbreak of war in 1914 Keay was made commandant of the Bangour War Hospital with the rank of lieutenant-colonel, and soon after the conclusion of hostilities in 1919 received the C.B.E. in recognition of his services. He contributed a number of papers to the literature of his specialty, and in 1918 achieved the highest honour in this field of medicine by being chosen president of the Royal Medico-Psychological Association. Keay was a rather shy man, but he was even-tempered and extraordinarily diplomatic and tactful in dealing with those with whom he was associated. He was fond of outdoor sports, was a fine companion, and notwithstanding his long residence in Scotland he never lost the Irish brogue in his speech. He is survived by his wife, who was a daughter of Dr. Rutherford of Crichton Royal, Dumfries.

A. M. WATTS, M.D., D.P.H.

We regret to announce the death at his home in Broadstairs on Jan. 23 of Dr. A. M. Watts. Born in 1871 and educated at the Royal Academy, Gosport, and University College, London, Alexander Minter Watts qualified M.R.C.S. and L.R.C.P. 1894. After a few years in general practice he studied at Newcastle-upon-Tyne, obtaining the M.B., B.S.Durham in 1901 and the M.D. of that University in 1903. He was early attracted to public health work, and while in general practice at Minster was a member of the Isle of Thanet Rural District Council and Board of Guardians. In 1912 he obtained the D.P.H. and took a whole-time appointment with the Kent County Council. After the last war, in which he served in the R.A.M.C., he was appointed medical officer of health of the East Kent (No. 1) United District, which post he held until last December, when he retired owing to failing health. Dr. Watts was well known not only to all his colleagues in the area but also over a large part of Kent. He was an active member of the B.M.A., serving on the Kent Branch Council and also as chairman of the Isle of Thanet, later the East Kent, Division from 1933 to 1936 and again in 1942. His nomination as president of the Kent Branch in 1935 was for him a just recognition of many years of good work for the medical profession in the county, and he greatly appreciated the honour. In 1938 he was elected member of Council of the B.M.A., representing Kent and Sussex. Among a number of other activities was his interest in the National Association of Local Government Officers, and he was president of the Thanet Branch for several years. Although in failing health Dr. Watts carried on for as long as possible owing to the shortage of doctors, and he will be greatly missed by all those who knew him as a friend or adviser. He is survived by his widow.

Dr. **Selwyn Hale Puckle** died at Church Stoke, Montgomeryshire, on Dec. 13, 1942, aged 83. Born at Hamilton, Victoria, Dr. Puckle was educated at Gelong Grammar School and came to this country in 1878. He took his B.A. at Trinity Hall, Cambridge, in 1881 and qualified M.B., C.M. at Edinburgh in 1885. The following three years were spent in house appointments and assistantships in Edinburgh, and then he settled in Bishop's Castle, Salop, where he stayed until he retired in 1919. He had the esteem and respect of the population of a very extensive district. In addition to his professional duties he found time for much public work. He was mayor of the borough in 1899 and from 1910 to 1914, and took a keen interest in the life of the district, even after he retired, until failing health cut him off from active work three years ago. He took part in all kinds of sport and enjoyed shooting up to a few years before his death. He was a member of the B.M.A. from 1888 to 1919 and was president of the Shropshire and Mid-Wales Branch in 1909-10. His wife, whom he married shortly after coming to Bishop's Castle, died in 1939, and his later years were saddened by the absence abroad of his three sons—two in India and one in Hong Kong who is now a prisoner in Japanese hands.

Dr. **John Lewis Jones** of Llansamlet, Swansea, died suddenly at his home on Dec. 14, 1942, at the age of 78. Dr. Jones was born at Llanon, Cardiganshire, and was educated at Christ College, Brecon, and Edinburgh University, qualifying M.B., C.M. in 1891. From the time he qualified until 1935 he practised in Llansamlet and district, where he was both physician and friend to large numbers of the inhabitants. He held all the local medical appointments, and was made J.P. for the Borough of Swansea in 1919. He was twice married, both wives predeceasing him; there were no children. Dr. Jones had been a member of the B.M.A. for 39 years.

We regret to announce the sudden death on Jan. 29 after a short illness of Dr. **Alfred Adams** of Knutsford, Cheshire. Taking up medicine rather later than most, Alfred Adams qualified M.B., Ch.B. with honours at Liverpool University in 1910; two years later he took both his M.D. and the D.P.H. He held the Johnston Colonial Fellowship in Pathology and Bacteriology at Liverpool for a year before being appointed medical superintendent of the Liverpool Sanatorium, Delamere Forest, in 1912, a post from which he retired after twenty-six years' service on reaching the age limit in 1938. Dr. Adams was in many ways a pioneer in the early institutional treatment of pulmonary tuberculosis, and conducted the often difficult work of the sanatorium with ability and initiative. As far back as 1913 he was writing on induced pneumothorax in this disease. During the last war, in which he served with the rank of captain, he was in charge of No. 2 Mobile Bacteriological Laboratory in Salonika and served also in Gallipoli. He was a regular attender at medical meetings in the North-West, and for two years was president of the North-Western Tuberculosis Society. With the outbreak of the present war he came out of retirement and took up work as District Tuberculosis Officer under the Cheshire County Council.

Dr. **Charles John Girling**, who has died at Stratford-on-Avon, was the son of a North Country clergyman and was educated at Guy's Hospital. After qualifying in 1889 he went to Leeds, where he was associated with the late Lord Moynihan as assistant to Mr. Jessop, the celebrated Yorkshire surgeon. Later he went into general practice at Batley, and early this century he came south and worked for thirty years in a rural district in Dorset. He was a member of the B.M.A. for thirty years, and in 1930 was president of the Dorset and West Hants Branch. Essentially a quiet and unassuming man, Girling became the guide, philosopher, and friend of several generations of Dorset folk, and it was characteristic of him that when acknowledging some gifts from his friends on his retirement he used the phrase: "I've never been anything special." It will be a long time before this simple man with his simple pleasures and simple philosophy will be forgotten by his wide circle of friends.

We regret to announce the death at Bristol on Jan. 13 at the age of 74 of Dr. ISIDOR FISCHER, an eminent medical historian and gynaecologist, formerly a privat-dozent of Vienna. He was a prolific writer on the history of medicine, but his chief works were his *Lexicon of Eminent Doctors in the Last Fifty Years* (1932-3) and *Eponyms in the Terminology of Disease* (1932), two of the most useful books of reference that a medical library can possess. He contributed two valuable articles to Halban and Seitz's *Biology and Pathology of Women*—namely, "The History of Gynaecology" (1924) and "A Retrospect of the Progress of Obstetrics and Gynaecology in the Nineteenth Century" (1929). He was also the author of the *History of Obstetrics in Vienna* (1909), *Medical Deontology* (1912), and the *History of the Medical Society of Vienna, 1837-1937* (1938). He settled in this country in 1938, where he continued his studies in a more sympathetic atmosphere than in Vienna, and the following year was elected an honorary member of the Section of the History of Medicine of the Royal Society of Medicine.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

At a Congregation held on Feb. 6 the following medical degrees were conferred:

M.B., B.CHIR.—D J Bauer, D. M Jeffreys, S. J R. Macoun, Yok Hing Ng, P H. Sanderson, I. MacN Smith, P H S Hooper, J N. Agate, G G. B Blackman, P. D. Eeman, D I. Lishman, E J T Prettejohn, F. K. Lau, *T. S Hindle, *L. A. S White.

*In person

In the schedule to Regulation 26 for Degrees in Medicine and Surgery relating to exemptions from the First M.B. Examination, the Faculty Board of Medicine has substituted "The Intermediate Examination in Science of any University in Great Britain or Northern Ireland" for "The Intermediate Examination in Science in the University of London or Wales."

UNIVERSITY OF BIRMINGHAM

The Council of the University has recently converted the Readership in Pharmacology into a Chair of Pharmacology and has promoted Dr. Alastair C. Frazer to the professorship. Dr. Frazer has held the readership for rather more than 12 months.

UNIVERSITY OF SHEFFIELD

Dr. Helen P. Uprichard has been appointed an assistant tutor in medicine.

ROYAL COLLEGE OF PHYSICIANS OF LONDON

A Comitia of the College was held on Jan. 28, when, the President, Sir Charles Wilson, being abroad, the Senior Censor, Sir Henry Tidy, was in the chair. The following Fellows were appointed representatives of the College: Sir Robert Hutchison on the Aliens Committee; Prof. F. R. Fraser on the Poisons Board; and Sir Arthur MacNalty and Prof. J. W. McNee on the Imperial Cancer Research Fund. The chairman reported that a message of greeting had been sent to the National University of Chile, which celebrated its centenary by holding a First National Congress of Medicine.

Prof. M. Greenwood will deliver the FitzPatrick Lectures on "Medical Statisticians from Petty to Farr" on Feb. 9 and 11; Dr S. A. Henry the Milroy Lectures on "The Health of the Factory Worker in Wartime" on Feb. 23 and 25; Prof. R. V. Christie the Goulstonian Lectures on "Emphysema" on March 4, 9, and 11; Dr. Geoffrey Evans the Lumleian Lectures on "Arteriosclerotic Disease" on March 16 and 18; Prof. G. W. Pickering the Oliver-Sharpey Lectures on "The Circulation in Arterial Hypertension" on March 23 and 25; and Air Commodore Symonds the Croonian Lectures on "Flying Stress" on May 25 and 27.

The following candidates, having satisfied the Censors' Board, were admitted Members of the College:

D. S Cadman, M B.Camb., D R. Cameron, M D.St. Andrews, E D H. Cowen, M B Camb., F. C Deller, M D Liverp., W. Fine, M B Lond, Frances V Gardner, M B Lond., W. P. U Jackson, M.B Camb, D S. Lewes, B.M Oxon, D. de la C. MacCarthy, M D.Lond., Surg. Lieut. R N.V R., M E. MacGregor, M.B.Lond, Surg. Lieut., R N., E. A. Spriggs, B M Oxon, Lieut., R.A M.C., T. C. Studdert, M B Durh.

Licences to practise were granted to the following 221 candidates (including 24 women) who had passed the Final Examinations in Medicine, Surgery, and Midwifery of the Conjoint Board, and have complied with the necessary by-laws:

J. D. Abbott, J. M. Allcock, P S. Allenby, D Annis, N Arenstein, J. K Arkle, F. R. St. C. Assinder, E. H Back, Muriel I. I. Baird, T. E Bairstow, J. F. Baker, T. M. Ball, D. R. Barnes, Joan E. Barter, N. I Bartholomew, H. C Bergmann, Margaret E. Berry, Isobel P. Beswick, J. W. Betts, Rosemary P. Biggs, P. R Birks, P. Ll. Blaxter, D. H Bodger, C. Boroda, J P. Bound, R E. Bowers, J. R. Briggs, F. S. W. Brimblecombe, F. B Bromfield, F. H Budden, J. D. Buxton, C. Campion, S L. Carey, C. B. Cartledge, W. F. Cavenagh, A. H Cheshire, J M. Childs, S. M Chris, G H V. Clarke, R. B Coles, M. C Connell, W. D. D. Cooke, T A. Copp, A. K. Cumming, F A. L. Da Cunha, Elisabeth Dalley, K. H. Dalrymple, I. E. Davidson, D. I. Davies (died Jan 3), R. G Davies, Jesser S Davis, J T Dawson, L. F. Demetrius, P F G. Denton, J. Douglas, W. K. Douglas, A. H Drewitt, J A Easom, C. D. Edwards, A J. Eley, T. H. Elias, F. R. Ellis, I. C W. English, G. L. Evans, G. M. Evans, T. G. Evans, Alianore M. C Fairfax-Lucy, H. C Faulkner, J. F. A Fenton, P F G Finch, R. A. Fisher, H T. Foot, Kate Forrest, T. C. Fort, A R Fox, H G. Frampton, Catherine J. S. Gauvain, T. A L Gethin-Jones, D S. Gibbs, R A. de K Glover, F J Goddard, S. Goldman, H Goldstein, Eva M. Graves, F. T Graves, A J. Gray, F W. M Greaves, R F Griffith-Evans, F D. Griffiths, R W. Griffiths, S. D. Gun-Munro, M. J. L. Hassall, P. E Helme, A. G Healing, G C Hickie, A. R H Hicks, Hazel B. Hill, J L. Honig, G. A. N Horton, J G. Howells, A. J R Hudson, F. P. Hulke, W. H Humphreys, R J Jameson, E S. Jardine, Margaret M G Joad, E L John, Kathleen E. J Jones, P. G. Keates, Margaret Kemsley, H. W H Kennard, R. A. H Kinch, E J King, H. E. Knowles, S. Kramer, R Lake, C. L S Lambert, Kathleen M Lane, P. L Langton-Lockton, H J C J L'Etang, W J Lewis, M. Lindner, J Littler, R. E. Loder, T. G. E. Loosemore, A MacL Macarthur, R I McCallum, K. McGlashan, L. S. MacLeod, I P Madhok, H. J. Markham, B P. Marmion, A. S Mason, C J Mathes, R H Maudsley, D G Maurice, S. R Mawson, F S Mellows, Jessica Mestel, J. R. Moffat, P A. G Monro, R J Moolan-Feroze, H C Moore, R. Morris, K E. Mortimer, M. F Morton, J R Napier, G. D K Needham, C T. Newnham, R. D Nicholson, N Noble, Rhona M Oliver, H B F. Ordish, L R B Parker, R T Parkin, P R P. Pearsall, J. G. Pegg, E J. Perks, D. J Petit, L Posner, R B Raffle, A. J H. Rains, G. S. Ramsay, C. R. McD Redwood, W. T Rees-Jones, C A. I. Reis, S M A. Rizvi, J A. Robertson, H M. Robinson, Edith M Robson, E Roebuck, J. Ronchetti, J. P I Rose, A. J E Rowe, P Rowntree, I A. Roxburgh, T J. Ryan, A. P. S Sanders, H T N. Sears, J Sebel, F O J Shaw, G N Shone, M. Singh, E G Sita, B. F Smallhorn, E S O. Smith, F. M. Smith, T P Smith, V O G Smyth, P Solnik, E M. Southern, G Steiner, D G H Stone, B Sullivan, F. R. Sutton, N W Tattersall, G W Taylor, L B Thomas, M. V P Thomas, J D Thompson, W B Thompson, Dorothy H Thorne, B E. Tomlinson, Edith M M. Toye, Joan D Trethowan, W H Trethowan, G. C Turner, Ll. R Twentyman, Elizabeth Tylden, F. L. A Vernon, J. A Vyse, E Waddington, I R Waters, G. Watkinson, H Weinreb, J A T West, A N Whiteside, D. H J Williams, H. O Williams, H. A G Winter, Celestina M Xavier

Diplomas in Public Health were granted, jointly with the Royal College of Surgeons of England, to the following successful candidates:

M R Blair, S. D. Elek, Ll M Franklin, A Jephcott, N J S Nathan, B F O'Flynn, T. G Osler, B. F Russell, A. E. Tinkler.

Diplomas in (*a*) Anaesthetics (27), (*b*) Psychological Medicine (10), and (*c*) Laryngology and Otology (7) were granted to the successful candidates whose names were printed in the reports of the meetings of the Royal College of Surgeons of England in the *Journals* of Dec. 26 (p. 770), Jan. 30 (p. 147), and Jan. 30 (p. 147) respectively

ROYAL COLLEGE OF PHYSICIANS OF EDINBURGH

A quarterly meeting of the College was held on Feb. 2, with the President, Dr. Charles McNeil, in the chair. Dr. John George Sclater (Edinburgh), Dr. Adam Patrick (Dundee), and Dr. John William McNee (Glasgow) were introduced and took their seats as Fellows of the College. Dr. John Alexander Mortimer (Hamilton), Dr. George Alexander Grant Peterkin (Edinburgh), Dr. James Ronald (Stirling), and Dr. Thomas Alfred MacGibbon (Norfolk) were elected Fellows of the College.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

Dr. George Graham will deliver the Finlayson Memorial Lecture on "Various Hypotheses on the Causes of Diabetes Mellitus" in the hall of the Faculty (242, St. Vincent Street, Glasgow) on Wednesday, Feb. 24, at 4 p.m.

The Services

Air Vice-Marshal A. GRANT, C.B.E., R.A.F., has been appointed Honorary Surgeon to the King in succession to Air Vice-Marshal W. Tyrrell, C.B.E., D.S.O., M.C., R.A.F. (ret.).

Prob. Temp. Surg. Lieut. A. E. DE LA T. MALLETT, R.N.V.R., has been awarded the D.S.C. for bravery and enterprise when a west-bound enemy convoy was intercepted off Dieppe by our light naval forces and one supply ship and one escorting ship were sunk and others damaged.

The M.C. has been awarded to Capt. W. H. Campbell, A.A.M.C., and to Capt. M. H. K. Haggie and Lieut. C. G. Rob, R.A.M.C.

Flying Officer A. J. F. Eberle, R.A.F.V.R., has been appointed M.B.E. The official citation in the *London Gazette* of Jan. 26 reads as follows:

> "One day in Nov., 1942, when two aircraft were taking off in formation, the one leading struck another which was standing on the side of the runway, causing it to be thrown into the path of the second aircraft which was taking off. The three aircraft caught fire and the pilot of the second aircraft in the formation was stunned and trapped in his cockpit by the hood, which had become locked. Fire engines which came to the scene immediately were unable to subdue the flames. At this stage F/O. Eberle and an Army officer leapt on to the wing but, despite frantic attempts to open the cockpit hood, they were unable to do so before being forced to retire owing to the flames. Seizing an axe, these officers returned to the aircraft, which was burning furiously with ammunition exploding in both wings, and succeeded in smashing a panel. An airman then leapt on to the wings and with great presence of mind pulled the hood release, enabling the two officers to extricate the pilot from the blazing aircraft. F/O Eberle and his Army companion displayed outstanding courage and complete disregard of their safety in saving the pilot from certain death."

CASUALTIES IN THE MEDICAL SERVICES

The name of Temp. Surg. Lieut. J. E. Powell, R.C.N.V.R., is included in an Admiralty Casualty List, published on Jan. 29, among the officers of H.M. Aircraft Carrier *Avenger* who are reported "missing, believed killed."

Prob. Temp Surg. Lieut. **Robert Rosie Latto**, R.N.V.R., is included as "missing, presumed killed" in an Admiralty Casualty List published on Feb. 5. He was born on March 17, 1918, and was educated at Cardiff, qualifying M.R.C.S., L.R.C.P. in 1941 and taking the degrees of M.B., B.S. of the University of London in the same year. Before entering the R.N.V.R. he held a post at the Prince of Wales Orthopaedic Hospital, Cardiff.

Capt. **Frederick Hunter**, I.M.S., who died in India on Jan. 22 as the result of an accident, was educated at the University of Aberdeen, where he graduated M.B., Ch.B., in 1926, proceeding M.D. (with commendation) in 1934. Before entering the I.M.S. as Temp. Lieut. in Feb., 1942 (with seniority Aug., 1935), he held house posts at Perth and Rochdale Infirmaries and from 1929 to 1936 was in practice at Turriff, Aberdeenshire. In 1936 he moved to Worthing, where he was in partnership with Dr. John Ferries. He had been a member of the B.M.A. since 1928.

Prisoners of War.—Lieut.-Col. J. Bennet, R.A.M.C., Surg. Cmdr. H. L. Cleave, R.N., Capt. E. K. Cruickshank, R.A.M.C., Major J. W. D. Goodall, I.M.S., Capt. F. J. W. Hooper, R.A.M.C., Capt. J. G. Jesson, R.A.M.C., Col. V. H. Wardle, M.C., T.D., Capt. A. J. N. Warrack, R.A.M.C., Capt. R. B. C. Welsh, R.A.M.C.

Wounded.—Capt. J. C. Bishop, R.A.M.C., Capt. M. S. Chayen, R.A.M.C., Capt. E. P. Johnson, R.A.M.C., War Subs. Capt. J. S Martin, R.A.M.C., Capt. B. E. Miles, R.A.M.C., War Subs. Capt G. R. Wightman, R.A.M.C.

Missing.—Lieut.-Col. (Acting Col.) K. P. MacKenzie, R.A.M.C., Capt. E. J. A. Needham, R.A.M.C., Surg Lieut. N. J. W. Smith, R.N.

DEATHS IN THE SERVICES

Col. **James Henry Robinson Bond**, C.B.E., D.S.O., late R.A.M.C., died at Cheltenham on Jan. 14, aged 71. He was born on July 21, 1871, qualified M.R.C.S., L.R.C.P., in 1898, and entered the R.A.M.C. in the following year. He served in the South African War of 1899–1902, receiving the Queen's Medal with six clasps and the King's Medal with two clasps. During the war of 1914-18 he served in Mesopotamia from 1915 to 1918; was mentioned in dispatches, and was awarded the D.S.O. in 1917 and the C.B.E. in 1919. He retired in 1924, and latterly had been a confirmed invalid.

Lieut.-Col. **John Lawrence Wood**, O.B.E., R.A.M.C. (ret.), died at Rosslyn Castle, Midlothian, on Jan. 4, aged 60. He was born at Darlington and was educated at the University of Cambridge and at St. Bartholomew's Hospital, taking the B.A. in 1902 and the M.R.C.S., L.R.C.P. in 1906. He entered the R.A.M.C. and served in India and, during the war of 1914-18, in France, and was awarded the O.B.E. for his services. He retired in 1927 but was re-employed on the outbreak of the present war in Sept., 1939, in the Scottish Command, reverting to retired pay in July, 1940. He is survived by two sons, the elder of whom is serving in the R.A.M.C.

Lieut.-Col. **Wilfrid Wynne Jeudwine**, C.M.G., I.M.S. (ret.), who died at Eastcote, Middlesex, on Jan. 22, was born on May 19, 1877, and was educated at the University of Cambridge and at St. Bartholomew's Hospital. He graduated B.A. in 1898, and qualified M.B., B.Chir., and M.R.C.S., L.R.C.P. in 1902, proceeding M.D. in 1912 and taking the F.R.C.S.Ed. in 1933. He entered the I.M.S. in 1902 and had a distinguished career in both the military and civil branches of the Service. In 1908 he served with an expedition on the North-West Frontier of India, receiving the medal with a clasp. In the war of 1914-18 he served in France and Belgium, was mentioned in dispatches, and was awarded the C.M.G. in 1916. He held the important civil posts of professor of ophthalmic surgery at King Edward's Medical College, Lahore, in 1920-1, of civil surgeon at Jullunder in 1922, chief medical officer in the Delhi Province in 1922-3, and civil surgeon at Simla West from 1923 to 1925. He was promoted lieut.-col. in 1922 and retired in 1928. He was author of the *Handbook for Compounders in Civil Hospitals and Sub-assistant Surgeons in Outlying Districts*. After his retirement he was for a time school medical officer at Newport, Isle of Wight, and more recently was in practice at Eastcote. He had been a member of the B.M.A. for 27 years.

Medical Notes in Parliament

Treatment of Venereal Diseases in the Army

Replying to Dr. Morgan on Jan. 28, Sir **James Grigg** said sulphapyridine and sulphathiazole were recommended by the War Office for the treatment of gonorrhoea; neo-arsphenamine, bismuth, and in some cases mapharside for the treatment of syphilis. Specific and general instructions on treatment had been issued to all medical officers, and comprehensive notes on these diseases had also been issued for their guidance. The drug treatment was in general the same in the American and Canadian armies, but differed in some details. A good supply of all these drugs was available. Answering Mr. Groves on the same date, Sir **James Grigg** said King's Regulations laid down that commanding officers should ensure that all men were medically inspected not later than the morning after rejoining their units from furlough. He was satisfied this was in general carried out. Officers returning from leave did not automatically undergo a medical inspection.

British Hospital in North Russia

Mr. **Noel-Baker**, replying to Commander Bower, said that late last summer the British Government arranged for the establishment of a British hospital unit in North Russia. This unit, which was staffed by British Naval officers and ratings, now dealt with all sick and wounded British merchant seamen at Murmansk. The Soviet Government had agreed in principle to the establishment of a second British hospital unit at another port in Northern Russia.

Skin Diseases among Troops

On Feb. 2 Sir **James Grigg**, replying to Captain C. S. Taylor, said that 23 officers and 198 other ranks were returned from the Middle East in 1942 with skin diseases. It was not known how many of these contracted the diseases before they left this country, but the number was likely to be very small. He was satisfied that a very complete system of medical inspection of troops going over-seas was in operation, and that no one suffering from a serious skin disease was sent abroad.

Plan of Medical Officers of Health

During the debate on economic policy after the war, in the House of Commons on Feb. 2, Mr. **Pethick-Lawrence** expressed his pleasure on seeing in the Press that day a report issued by the Society of Medical Officers of Health, which stated: "A national medical and health service should be established on a whole-time salaried basis with the complete facilities outlined in this report. Private enterprise cannot provide and maintain complete hospital, medical, and allied services." He had, he added, seen other statements by eminent doctors and he thought, by bodies representing the doctors, bearing that out

Medical Services for Ethiopia

Mr. **Eden** announced on Feb. 3 that at the request of the Emperor of Ethiopia a senior member of the Colonial Medical Service was seconded on Feb. 1, 1942, for service under the Emperor, who appointed him Director-General of the Ethiopian Medical Services. At the request of the Ethiopian Government the names of four senior non-British doctors had been proposed to them for medical appointments. Every effort had been made and would be made, within the limits imposed by the man-power situation in this country, to meet the Ethiopian Government's further requirements. In addition the British Red Cross maintained a hospital in Addis Ababa. The Friends Ambulance

Unit had recently dispatched an important unit of doctors and medical assistants to undertake medical work in the capital and in the provinces. They had also supplied considerable quantities of urgently needed drugs.

Maternity Beds

Mr. ERNEST BROWN told Dr. Summerskill on Feb. 4 that during 1942 the maternity beds in the L.C.C. hospitals were increased by approximately 220, bringing the total number to approximately 627. During the same period the maternity beds in the voluntary hospitals in the county of London were increased by 165, bringing the total number to approximately 515. These were in addition to the 2,700 beds in emergency maternity homes in reception areas and the houses in the country to which many London homes had been removed. Both the L.C.C. and the voluntary hospitals hoped to provide more maternity beds in the near future if staff could be found.

No Special Diagnostic Service for Wales

Sir HENRY MORRIS-JONES asked on Feb. 4 whether the Minister of Health would make arrangements for the provision of free diagnostic assistance for young insured persons between the ages of 15 and 25 in Wales who were referred to the Regional Medical Service by their panel doctor, and, where necessary, hospital and convalescent home treatment in a State-aided hospital on the lines of similar provision by the Scottish Department in the Clyde Valley. Mr. BROWN replied that the staff of the Department's Regional Medical Service was engaged on war duties, and consequently the procedure to which Sir Henry referred was not practicable in England and Wales. Diagnostic and other facilities of hospitals in England and Wales had been augmented in a number of ways under the Emergency Hospital Scheme. He had no reason to suppose that they were not available to patients referred by their doctors.

Cost and Staffing of Medical Boards

Mr. BEVIN stated that between July, 1940, and Dec. 31, 1942, the average number of medical practitioners serving on medical boards was 3,418, the largest number at one date being 3,781, and the smallest 3,014. Between the outbreak of hostilities and Dec. 31, 1942, approximately £2,770,000 was paid in fees and travelling expenses to chairmen and members of civilian medical boards and to consultant examiners. These payments related to examination of persons called up under the National Service Acts for service in the Forces or in Civil Defence and of those volunteering for service in the Forces.

Cottages for Farm Workers

On Feb. 4 Mr. BROWN announced that the Government had authorized preliminary arrangements for the building by local authorities of a limited number of cottages for farm workers. Increased food production had aggravated the existing shortage and the cottages would be built where the need was most acute. Preliminary preparations were being made on the basis of 3,000 cottages.

Vaccinia and Small-pox Deaths.—On Jan. 19 Mr. ERNEST BROWN told Mr. ALFRED EDWARDS that 6 deaths were registered in England and Wales during 1941 of which the causes were certified as vaccination, vaccinia, or other sequelae of vaccination The sexes and ages of the deceased were 3 males aged 5 months, 19 years, and 30 years, and 3 females aged 9 weeks, 5 months, and 2 years. In addition, inquiries resulted in one other death certified as due to meningo-encephalitis being classed to vaccinia. The deceased was a male aged 29 years. Mr. BROWN also informed Mr. Edwards that no death from small-pox was registered in England and Wales during 1941.

Maintenance of Cancer Patients—Mr. HARVEY inquired on Jan 21 whether, in view of the fact that free maintenance in hospital had been extended to tuberculous patients and of the importance of encouraging sufferers from cancer to seek early treatment, a similar provision could be made in their case. Mr. BROWN replied that the distinction in payment for hospital treatment between infectious diseases (of which tuberculosis was one) and non-infectious diseases (of which cancer was one) was a matter of statutory requirement. In deciding whether any charge should be made in an individual case of the latter type local authorities were authorized to have regard to the financial circumstances of the individual. He had no reason to suppose that individuals were deterred from undertaking treatment by any difficulties on this account.

Medical Staffing of Appeal Tribunals.—Sir WALTER WOMERSLEY estimates that to staff the suggested pensions appeal tribunals, including the additional appointments which would have to be made to his own staff, between 35 and 55 whole-time doctors would be required. He added that the British Medical Association was last consulted on this matter on Nov. 27 last.

Medical Referees for War Workers.—In reply on Jan 21 to Miss Ward, Mr. ERNEST BEVIN announced that after consultation with the British Medical Association and Local Medical War Committees, he had appointed medical referees who, among other things, examined workers who sought permission on medical grounds to leave employment which was scheduled under an Essential Work Order but could not produce satisfactory medical evidence. He was also arranging for these medical referees to examine workers in certain circumstances where the employers wished to discharge them on medical grounds.

Mines Medical Service.—On Feb. 2 Major LLOYD GEORGE told Mr. Lipson that 207 applications were received from doctors for posts under the Ministry of Fuel and Power for the Mines Department Offers of appointment had been made to six of the applicants, and the selection of candidates for the remaining three posts would be made in the near future.

Parliamentary Medical Committee—The Parliamentary Medical Committee met on Feb. 2, Sir Francis Fremantle in the chair, and discussed the shortage of medical men for public services and in particular for the Indian Medical Service.

Notes in Brief

It has been decided to bring into operation, as soon as the necessary arrangements can be made, the Child Adoption (1939) Act.

It is estimated that over 90% of the milk sold in London for domestic consumption is pasteurized Mr. Mabane denied on Feb. 3 that a decision had been taken to make compulsory the pasteurization of raw milk.

Introduction of oatmeal into the national loaf is in progress.

Medical News

The spring programme of Chadwick Public Lectures, arranged by the Chadwick Trust (204, Abbey House, Westminster, S.W.1), is as follows: Feb. 23, 2.30 p.m., at London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, W.C., Prof. M. Greenwood, F.R.S., "Social and Industrial Environment and Disease"; March 16, 2.30 p.m., at Royal Society of Tropical Medicine and Hygiene, 26, Portland Place, W., Dr. R. Cruickshank, "Some Post-war Problems in the Control of Infectious Diseases"; April 6, 2.30 p.m., at Royal Sanitary Institute, 90, Buckingham Palace Road, S.W., Mr. T. Sharp, "Town Planning and Public Health"; May 11, 2.30 p.m., at Royal Society of Tropical Medicine and Hygiene, Dr. C. F. White, "Health Problems in Rebuilt London"; June 17, 4 p.m., at Chelsea Physic Garden, Swan Walk, S.W., Mr. F. J. Chittenden, "Plants causing Irritation." Admission to the lectures is free and further particulars may be had from the secretary of the Trust.

The President and Council of the Geological Society of London, Burlington House, London, W.1, extend a cordial invitation to any members of the Association who would care to attend their next ordinary general meeting, to be held on Wednesday, Feb. 24, at 3 p.m. There will be a discussion on some medico-geological problems, and the following communications will be read: "Human Fluorosis," by Drs. D. C. Wilson and M. M. Murray; "The Radiology of Human Fluorosis," by Dr. F. H. Kemp; "Molybdenum as the Cause of Teart Disease," by Dr. A. H. Lewis; and "The Geological Aspects of Fluorosis and Molybdenosis, and Other Problems," by Mr. C. E. N. Bromehead, F.G.S.

The second meeting of the Pan-American Congress of Ophthalmology will be held in Montevideo from Nov. 4 to 7, 1943. One full day each will be devoted to social ophthalmology (including prevention of blindness and trachoma), papers on research work, clinical ophthalmology, and surgical ophthalmology. Manuscripts should reach the executive secretaries, Dr. Conrad Berens, 477, First Avenue, New York, U.S.A., or Dr. Moacyr E. Alvaro, Conselaçao 1151, Sao Paulo, Brazil, before June, 1943.

Twenty-six grants were made by the Ella Sachs Plotz Foundation for the Advancement of Scientific Investigation during 1942, two of them to workers in this country: Dr. V. Korenchevsky of Oxford and Dr. Hermann Lehmann of the Sir William Dunn Institute, Cambridge. The nineteenth annual report of the Foundation states that during the present great need for funds grants will be given in the sciences closely related to medicine without reference to special fields; the maximum amount will usually be less than $500. Applications for the year 1943–4 should be sent to Dr. Joseph Aub, Massachusetts General Hospital, Boston, Mass., before April next.

The Wellcome Foundation has presented medical supplies to the value of £2,500 to Mrs. Churchill's Aid to Russia Fund and a similar amount to Lady Cripps's United Aid to China Fund. Arrangements have been made for these medical supplies to be dispatched to Russia and to China at an early date.

A new hospital, costing nearly £250,000, has been opened at Bulawayo, where the European population has increased in the last ten years from 51,000 to close on 70,000. Treatment facilities for natives are also being extended; in 1932 there was 1 native clinic and in 1941 the number was 53, and 10 have been built since; in-patients in 1941 numbered 45,948, as against 757 in 1932.

A meeting of the Fever Hospital Medical Service Group will be held in the Lecture Theatre at the London School of Hygiene, Keppel Street, Gower Street, London, W.C.1, at 3 p.m. on Friday, Feb. 26. Prof. S. P. Bedson will open a discussion on "Practical Applications of Recent Virus Research in Infectious Diseases."

The Association of Austrian Doctors in Great Britain (affiliated to the Free Austrian Movement) have arranged for a lecture to be given by Dr. Francis Bach on Sunday, Feb. 28, at 11.30 a.m., at 69, Eton Avenue, London, N.W.3 (near Swiss Cottage station)—the subject being "Rheumatic Diseases: Their Recognition and Treatment."

Speaking in Edinburgh last week, Dr. Andrew Davidson, Chief Medical Officer of the Department of Health for Scotland, made a plea for the fuller use by mothers of the orange juice and cod-liver oil provided under the Ministry of Food's scheme. Last month apparently only 21.6% and 16.8% respectively of those entitled to these important vitamin vehicles took advantage of the scheme.

Medical officers of health are now asked to notify the Ministry of Health of any women in their areas born in 1923 who have a history of tuberculosis. Form T.147 (W) should be used as before.

East Anglia and Bucks-Berks-Oxfordshire are the two latest areas in which hospital surveys are being undertaken by the Ministry of Health and the Nuffield Trust. This brings the number of surveys to date to six.

A sentence of nine months' imprisonment was passed at the Central Criminal Court on Jan. 13 on Dr. William St. John Sutton of Stepney for issuing false certificates to members of the Forces. He was also ordered to pay a sum not exceeding £50 towards the costs of the prosecution.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* during the week the notifications of infectious diseases went up with the exception of diphtheria and whooping-cough, with a fall of 189 and 51 cases respectively.

The rise in the notifications of paratyphoid fever, 32 cases, was due to an outbreak in Sussex, Hastings C.B., involving 27 persons—the largest outbreak for over twelve months.

There was a fall of 189 in the notifications of diphtheria, but the decline was not general, being contributed mainly by Yorks West Riding, Wales, Lancashire, and London with 71, 44, 37, and 26 fewer cases respectively.

The 51 fewer notifications of whooping-cough followed a continuous rise in incidence during the past month. The returns for Yorks West Riding fell by 52, and for Wales by 38, while those for Lancashire rose by 52.

The incidence of measles, after a reduction during the previous three weeks, has risen by 774 cases. In Yorks West Riding, however, the cases fell by 337. The largest of the increases were those of Yorks North Riding 218, Durham 155, and Gloucestershire 136. In the first county the rise was due solely to the experience of Middlesbrough C.B.

Dysentery notifications went up by 65 cases—almost 60%. New outbreaks occurred in Durham, Sedgefield R.D. 10, and Derbyshire, Derby C.B. 10. In Lancashire notifications mounted from 31 to 60, involving four county boroughs and four rural districts, the largest centres of infection being Manchester C.B. 18, Liverpool C.B. 7, Salford C.B. 8, Preston R.D. 15. Other important areas of infection were London 16, Surrey 17 (Epsom and Ewell M.B. 11), and Kent 17 (Maidstone M.B. 16).

In *Scotland* there was a rise of 47 cases in the incidence of acute primary pneumonia. During the past month the cases have been doubled, and in the week reviewed notifications in Glasgow went up from 139 to 186 and accounted for half the total cases in the country.

The recent outbreak of gastro-enteritis in St. Andrews, in which 110 persons were known to be affected, with 2 deaths, had its origin in sausage meat which had been heavily contaminated with an irritant poison.

In *Eire* only 4 cases of poliomyelitis were notified, the smallest number of cases for six months. During the height of the outbreak over 20 cases were reported each week.

Returns for the Week Ending February 6

The number of notifications of infectious diseases during the week in England and Wales included: scarlet fever 2,119, whooping-cough 1,695, diphtheria 897, measles 15,363, acute pneumonia 1,530, cerebrospinal fever 110, dysentery 89, paratyphoid 8, typhoid 9. In the great towns 109 deaths were recorded from influenza.

No. 4

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Jan. 30.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1943 (a)	1943 (b)	1943 (c)	1943 (d)	1943 (e)	1942 (Corresponding Week) (a)	1942 (b)	1942 (c)	1942 (d)	1942 (e)

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes paratyphoid A and B for Northern Ireland.

‡ Owing to evacuation schemes and other movements of population, birth and death ra es for Northern Ireland are no longer available.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, London, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.) Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

Telephone No.—B.M.A. and *B.M.J.*: EUSTON 2111.

Telegraphic Addresses.—EDITOR, *Aitiology Westcent, London;* SECRETARY, *Medisecra Westcent, London.*

B.M.A. Scottish Office: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Iron for Anaemia

Q.—*Anaemia of a mild type is common at present Which is the best of the iron preparations and in what form is it most effective? Is there any need to add copper or manganese to the ingredients of the prescription?*

A.—Ferrous sulphate is the best preparation of iron for use at present. It is most effective when given alone—tab. ferr. sulph. (*N.W.F.*) 3 gr. t.d.s., p.c.—but may be better tolerated in the form of Blaud's pill (pil. ferr. carb. 10 gr. t.d.s., p.c.). There is no need to add copper or manganese.

Prophylaxis for Hay-fever

Q.—*How early in the year should prophylactic treatment of hay-fever patients be begun? Is there any advantage in having a vaccine made from local pollen?*

A.—Inoculations with pollen extract for the prevention of hay-fever should begin in the last week of February. They should be given every five days with increasing dosage until the limit of tolerance is reached. As a precaution against reaction three minims of adrenaline chloride (1 in 1,000) should be injected with the extract. Extracts made from local pollens have no advantage over stock preparations. Thus Timothy pollen extract desensitizes to such different species as maize and bamboo pollen (Freeman).

Disposal of Person Dead from Notifiable Infection

Q.—*I had a patient aged five years who showed symptoms of cerebrospinal fever and died after an illness of two days. Of course I notified it to the M.O.H. Instructions were given to the undertaker that the corpse must not be taken into the church before interment. Is this precaution in the interest of public health necessary and usual? The sanitary authority states that after referring the matter to their M.O.H. they are satisfied the precaution was necessary and usual I have been M.O.H. to an urban district for over thirty years and have never taken these precautions and never heard of it being done before.*

A.—The general duty of preventing persons from coming into contact with, or proximity to, the body of any person who has died of a notifiable disease is imposed by section 164 of the Public Health Act, 1936, upon the person in charge of the premises where the body is lying. Such prevention might be taken to include removal to any other place except for purposes of burial or cremation, unless special precautions were taken. The more specific duty in relation to such bodies arises when the death from a notifiable disease occurs *in hospital* and the M.O.H. or other registered medical practitioner certifies that it is desirable that the body should not be removed except to a mortuary or place of burial or cremation. In such circumstances Section 163 of the Act prohibits, by inference, the body being taken to church. It has been quite usual for certificates of this kind to be issued by medical officers of health, or for the relatives or the undertakers to be advised that action on these lines will be taken if they persist in a proposal to hold a ceremony in church in the presence of the body. It may be noted that cerebrospinal fever is not a notifiable disease in the sense of the Act, but the Regulations (S.R. & O., 1912, No. 1226) relating to this disease extend all the relevant powers and duties contained in the Public Health Acts to it and poliomyelitis. It is a matter for the judgment of the M.O.H. whether he will exercise his certifying powers for all the diseases to which they extend, or take into consideration modern knowledge as to the transmission of the particular disease which has caused the death.

Healed Sacro-iliac Tuberculosis and Child-bearing

Q.—*Miss X is about to marry. She suffered from tuberculosis of the left sacro-iliac joint six years ago, but x-ray examination four years ago showed that complete recovery had occurred. In view of her history she sought my advice concerning pregnancy and possible complications. The questions are: (1) What, if any, is the risk of maternal trauma, or flare-up of tuberculosis in the healed joint? (2) What is the likelihood of birth trauma on account of contracted or unyielding pelvic ligaments—should labour be induced early? (3) What is the risk of tuberculosis in the offspring?*

A.—If there has been no clinical or radiological evidence of active tuberculous bone disease for more than five years, the likelihood of reactivation by pregnancy is slight. Patients suffering from ankylosis of the hip caused by tuberculous disease in childhood are commonly sent to maternity hospitals because of fear of difficulty in confinement, but I have never seen or heard of a case in which the disease has been reactivated. In the case of the sacro-iliac joint matters are somewhat different, for that joint is subjected to strain during labour; if, however, radiological examination shows that there is sound ankylosis, there should be little or no danger. (Active tuberculosis of bones or joints has an evil reputation in obstetrics, for often the disease is spurred into great activity and the patient sometimes succumbs to a miliary tuberculosis. This happened, for example, in the case of a patient who became pregnant some five years after a bone-graft operation for spinal caries.)

The second part of the question can be answered with more certainty. If the disease occurred before the pelvis reached adult size considerable asymmetry may develop; in the case of sacro-iliac disease, the symphysis pubis is pushed over to the sound side. On ordinary radiological examination these appearances may seem alarming, but in spite of the lop-sided look the dimensions may still be adequate and the pelvis retain a good obstetric value. Stereoscopic x-ray examination will give a better mental picture of the true size and form of the pelvis. Speaking generally, there need be no departure from ordinary obstetric practice with regard to delivery. The usual ante-natal examination for determining the presence of pelvi-foetal disproportion will, of course, be carefully performed.

The risk of tuberculosis to the offspring is remote; in this respect the outlook is more favourable than it is in the case of a mother suffering from pulmonary tuberculosis.

INCOME TAX

War Work Here by Irish Resident

G. M. J.'s home is in Ireland; he had retired but is in the United Kingdom doing war work. His wife continues to live in Ireland.

⁂ In such circumstances G. M. J. will be regarded as having a residence in both countries—i.e., one here and one which is available to him, whether in fact he uses it or not, in Ireland. He is, therefore, legally taxable by both countries, but under the statutory arrangements between them is entitled to the special relief provided for "double residents." The basis of this relief is that each country gives relief at one-half of the lower of the taxpayer's appropriate rates. For further information, and for any form which may have to be completed, G. M. J. should refer to his inspector of taxes.

LETTERS, NOTES, ETC.

Infant Feeding

Dr. Winifred M. Thompson (Onitsha, S. Nigeria) writes: I have just received the *Journal* of Dec. 12, 1942, and have read with interest Mrs. Nancy Salaman's letter on loneliness in infancy (p. 708). May I be permitted at this late date to make some comments? Mrs. Salaman expresses the wish that mothers would get back to what she calls "natural impulse" rather than be tied to the clock in the question of infant feeding. She gives the impression that in her opinion babies should be fed whenever the mother thinks that the baby's cries mean that it is hungry. Earlier in her letter Mrs. Salaman says that it often requires some experience to tell just why the baby is crying. If the mother is encouraged to feed her baby whenever she thinks that it is hungry, it will result in her feeding the baby whenever she cannot find any other obvious cause for the crying. Naturally the baby will not object, for all babies like to be picked up, and they do not mind having small feeds whenever they feel like it. Here in Nigeria the native women follow their "natural impulse" and feed their babies at any time. The result is deplorable. The babies are unhealthy and overfed, and they cry if their slightest wish is frustrated. Is it to this that Mrs. Salaman wishes us all to return? A normal baby will readily go three or four hours without food during the day and eight hours at night. If the baby is hungry before the next feed is due, surely the remedy is to increase his feeds. A baby responds to a regular routine, and is far more contented in consequence. Not only is it better for the baby, but it gives the mother a better chance to do all the work which she has to do and to take adequate rest, a point of the utmost importance.

VITAMINS AND PHYSICAL FITNESS

BY

A. A. HARPER, M.A., M.B., Ch.B.

I. F. S. MACKAY, Ph.D., L.R.C.P.I. H. S. RAPER, C.B.E., D.Sc., F.R.S.

Department of Physiology

AND

G. L. CAMM, M.A., D.Phil.

Department of Mathematics

Manchester University

The purpose of the present experiment was to test whether, as the result of a deficiency in the average student's diet, the fitness of University students has diminished since the beginning of the war.

Procedure of Experiment

In two groups of students the effects of adding vitamin supplements to the diet of one group were studied. Certain anthropometric data, "physical efficiency tests," and the incidence of minor ailments were used as a basis of comparison of the two groups. The experiment was performed on 69 subjects over a period of 21 weeks (April 18 to Sept. 11, 1942). The subjects were 40 R.A.F. and 29 R.E. cadets attending a special short course at Manchester University. The cadets had only recently joined the Forces, were all about the same age (18–19), and had roughly the same social background; they lived in two of the University halls of residence, and had the ordinary undergraduate diet: breakfast and supper in hall and a midday meal in the refectory at the University.

Examination.—The subjects were first examined by A. A. H. and I. F. S. M. The examination consisted of the usual anthropometric data: height (standing and sitting), weight, chest girths ("normal," expiration, and inspiration), the distance between the iliac crests, and the bi-trochanteric diameter. In addition the following measurements were made:

(*a*) The resting heart rate (4 successive half-minute periods after the subject had rested in the recumbent position for 15 minutes), the standing heart rate (4 successive half-minute periods immediately after standing up); and the effect of exercise on the heart rate (measured 0–15 and 60–90 seconds after stepping on and off a 40-cm. box 15 times in 30 seconds).

(*b*) The resting vital capacity (the maximum expiration following a full inspiration, the expired air being collected in a Hutchinson bell spirometer: four attempts were allowed, and the maximum recorded); and the post-exercise vital capacity (measured 30 seconds and 90 seconds after 40 knee-bends in 1 minute).

(*c*) The R.A.F. breath-holding and endurance tests The breath-holding test is the time in seconds during which the subject can hold his breath after a deep expiration followed by a full inspiration. In the endurance test the subject, with his nose clipped, expires deeply, and then, after a full inspiration, blows the column of mercury in a manometer steadily to a height of 40 mm. and maintains it at that level for as long as possible without breathing. The time during which the mercury column is sustained is measured in seconds, and the pulse rate for successive 5-second periods is noted during that time.

Vitamin Supplements.—The cadets were then divided into two groups. Group 1 (35 students) were given a daily vitamin supplement consisting of 6,000 units of vitamin A, 1,000 units of vitamin D, and 50 mg. of vitamin C, in the form of one "adexolin" capsule and one "celin" tablet daily. Group 2 (34 students), who acted as controls, received capsules of arachis oil and tablets containing citric acid, identical in appearance with those given to group 1 but devoid of any vitamin content. Each group contained half the R.A.F. and half the R.E. cadets; care was also taken to see that the men examined by A. A. H. and I. F. S. M. were equally divided between the two groups.

History of Minor Ailments.—A fortnight's supply of capsules and tablets was issued to the cadets at a time. Each cadet was interviewed by one of us every fortnight, when he collected a fresh supply of vitamins, and a history was taken of any minor complaints during the previous two weeks, particular attention being paid to respiratory and gastro-intestinal upsets and to bleeding from the gums.

Re-examination and Change-over of Groups.—At the end of 10 weeks (June 25) the cadets were all re-examined, the same routine being used as in the first examination. At the same time the two groups were changed over: group 1 were now given control tablets and capsules, and group 2 vitamin tablets and capsules.

Final Examination.—The experiment was continued for a further 11 weeks (until Sept. 11), and the examination of the cadets was again repeated. Each cadet was examined on all three occasions by the same examiner. The cadets were not told whether they were on vitamin or control tablets, and did not know of the change-over of the two groups half-way through the experimental period. The examiners did not know which of the cadets were on vitamin supplements and which were on control.

Results

The detailed analysis of the various sets of measurements was made by Dr. G. L. Camm. In addition to considering the vitamin and control groups during each half of the experiment and over the whole experimental period, a separate sub-analysis was made of the behaviour of the R.A.F. and of the R.E. cadets. In brief the main observations are as follows:

1. Minor Complaints

The average number of days of minor respiratory and gastro-intestinal complaints per man was estimated. These included acute and chronic colds, loss of appetite, "indigestion," and, occasionally, nausea and vomiting. The minor nature of most of the complaints must be emphasized; they were "subclinical" in the sense that only in a small minority were the subjects ill enough to stop work. We would emphasize also that these figures are compiled from the histories given by the subjects. Only in a few instances did we verify their statements by examination. Very few cases of bleeding gums were reported, and these have been omitted from the calculations. Complaints during the first fortnight of the experiment, and during the first three weeks after changing over the groups, were also omitted, as it was considered that during these periods there was not enough time for any possible protective action of the vitamins to become apparent. It was found that over the other 16 weeks of the experiment the control group showed an incidence of complaints 50% greater than the vitamin group. The total figures were: vitamin group, 671 days; control group, 1,015 days. The mean figures were: vitamin group, 9.7 days per man; control group, 14.9 days. Mean difference (vitamin − control): −5.2 ± 1.7. The difference between the two groups is statistically significant.

2. Physical Examinations

The means of the various measurements made during the three examinations were calculated, and examined to see whether there were any significant differences between the vitamin and control groups. There was no significant difference in respect of the anthropometric measurements (heights, weight, chest girths, and pelvic measurements). Nor were any significant differences found on comparing the standing pulse rate, the pulse rate during the R.A.F. endurance test, the post-exercise pulse rate, or the post-exercise vital capacity in the two groups. On the other hand, in four of the measurements made, interesting differences were found between the vitamin and control groups. These measurements were (i) the resting vital capacity, (ii) the breath-holding time, (iii) the R.A.F. endurance test time, and (iv) the resting pulse rate.

Resting Vital Capacity.—At the beginning of the experiment the mean resting vital capacity was the same for the two groups. At the end of the first half of the experiment the vital capacity of both groups had increased, but much more so in group 1 (vitamin) than in group 2 (control). At the third examination the vital capacity of group 1 (now control) had diminished, and that of group 2 (now vitamin) had increased. At both examinations, therefore, the balance of improvement was in favour of the cadets who had been receiving vitamins for the previous 10 or 11 weeks. The differences between the vitamin and control groups are statistically significant. A separate sub-analysis of the R.A.F. and of the R.E. cadets also reveals a significant difference between the vitamin and control groups in both cases. The results are shown in Table I and Fig. 1.

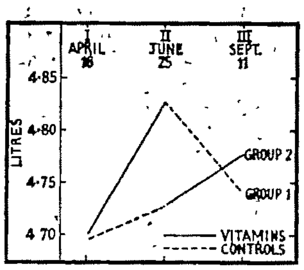

FIG. 1.—Resting vital capacity.

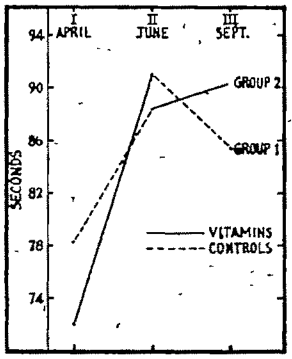

FIG. 2.—Breath-holding time

TABLE I.—*Resting Vital Capacity in Litres*

	1st Exam.	2nd Exam.	3rd Exam.
Group 1	4·698	(vitamin) 4 826	(control) 4·740
Group 2	4·694	(control) 4·727	(vitamin) 4·776

Whole period: Mean difference (vitamin − control) = +0 119 ± 0·022

Breath-holding Time.—The results resemble those of the vital-capacity measurements. At the end of the first half of the experiment the increase in breath-holding time in group 1 (vitamins) was much greater than in group 2 (control). At the end of the experiment, following the change-over of the two groups, the average time for group 1 had decreased, while that for group 2 had increased. At each examination, therefore, the cadets on vitamins showed a greater improvement than those on control tablets. Statistical analysis revealed a definitely significant difference between the vitamin and control groups of the R.A.F. cadets and a just-significant difference betwen the combined groups.

The results are shown in Table II and Fig. 2.

TABLE II.—*Breath-holding Time in Seconds*

	1st Exam.	2nd Exam.	3rd Exam.
Group 1	72·1	(vitamin) 91·0	(control) 85 4
Group 2	78·2	(control) 88·4	(vitamin) 90·3
Difference (vitamin − control):		+8·6 ± 3·7	+7·4 ± 3·9

Mean difference over whole experimental period (vitamin − control) = +8·0 ± 2·7

Endurance Test.—An examination of the times during which the cadets could maintain a column of mercury at a height of 40 mm. by a steadily exerted expiration shows changes similar to those in the breath-holding times, but less marked in degree. In each half of the experiment the group then on vitamins increased its time more than the control group. The differences are statistically significant only for the R.E. cadets. The results are shown in Table III and Fig. 3.

TABLE III.—*Endurance Test Times in Seconds*

Mean difference for R.E. cadets = +6·7 ± 1·8

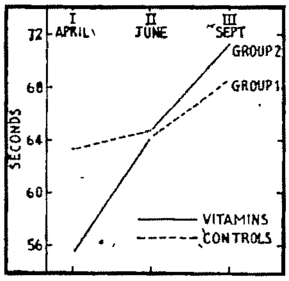

FIG. 3.—Endurance test.

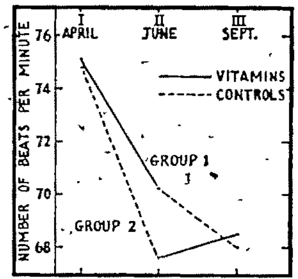

FIG. 4.—Resting heart rate.

Resting Heart Rate.—The changes in resting vital capacity and in the breath-holding and endurance-test times—showing in each a greater improvement in the vitamin than in the control groups—were such as might have been expected, assuming that the extra vitamins had increased the "physical fitness" either by diminishing the incidence of minor illnesses or by some other mechanism. The changes in the resting heart rate, however, were unexpected, if one accepts the popular view that a slow heart rate is a sign of "physical fitness." At the first examination the heart rates of both groups were practically the same. At the second examination the heart rates of both groups had diminished, but the slowing was more pronounced in the control than in the vitamin group. At the third examination it was found that the new control group showed a further diminution in heart rate, but the new vitamin group had increased in heart rate. The differences are statistically significant only in the R.E. cadets.

The results are shown in Table IV and Fig. 4.

Mean difference for R.E. cadets = + 4·5 ± 1·4

Discussion

The results of the experiment suggest that even during the summer months the diet of the students examined was sufficiently below the optimum level in respect of one or all of vitamins A, C, and D to produce a significantly greater amount of minor respiratory and gastro-intestinal upset than a similar diet supplemented with these vitamins. The greater improvement in resting vital capacity and in breath-holding and endurance times in cadets receiving vitamin supplements may be a reflection of this lessened susceptibility to minor infections, or may be due to some other action of the vitamins. The faster resting pulse rate in the cadets receiving vitamin supplements is difficult to explain.

The validity of these conclusions may be attacked on two grounds: first, that the number of subjects (69) was too small for an experiment upon nutrition and physical fitness; and, secondly, that the differences between the vitamin and control groups in vital capacity, etc., are not striking enough to warrant the drawing of any conclusions.

With regard to the second objection, Jokl, Cluver, Goedvolk, and de Jongh (1941), using a smaller group (32), found that repeated examinations of vital capacity and resting pulse rate showed mean figures varying only a matter of 20 to 30 c.cm. in the case of the vital capacity and fractions of one beat in the case of the pulse rate. All our variations are much greater than these.

The first objection (the paucity of numbers in the experimental group) is more valid. It is to some extent offset by the homogeneity of the group. All the cadets were of the same age, of the same social class, and during the experimental period were living under identical dietetic conditions. Another factor which increases the value of the observations is the striking manner in which the change over of vitamin and control groups half-way through the experiment in each case resulted in a reversal of the behaviour of the groups. This obviously increases the significance of the separate sets of observations, but no allowance for this was made in the computation of the results. The two halves of the experiment were treated separately, as if a second group of 69 students had been used for the second half. Had this actually been the case the differences obtained might well have been due to selection; but this can hardly be the true cause, since the same students were merely interchanged.

Despite these objections we feel that this report may be of value in drawing attention to a possible method of assessing the optimal rather than the minimal requirements of vitamins in the diet. A diet containing less than the optimum amount of a particular vitamin, while not producing a deficiency disease, may nevertheless give rise to a suboptimal physiological state which will only be revealed by the application of physiological tests such as we describe.

Summary

The effects of adding supplements of vitamins A, C, and D to the diet have been studied over a period of five months in 69 cadets living in university halls of residence at Manchester.

The cadets receiving vitamin supplements were less susceptible to minor respiratory and gastro-intestinal complaints than those receiving control tablets which contained no vitamins.

The group receiving vitamins showed a greater increase in resting vital capacity and in breath-holding and endurance times, and had a faster resting pulse rate than the control group.

We wish to express our thanks to Glaxo Laboratories Ltd. for facilitating the supply of vitamin and control tablets and capsules.

EFFECTS OF VITAMINS ON EXPERIMENTAL HYPERTHYROIDISM

BY

V. KORENCHEVSKY, M.D.

K. HALL, Ph.D.

AND

B. CLAPHAM, Ph.D.

(*From the Lister Institute, London**)

The problem of the relationship between thyroid hormone and vitamins is of great importance for the proper therapeutical application of these substances in several diseases and also for the treatment of hyperthyroidisms—in particular, Graves's disease. The existing literature on the subject is so large that economy of space unfortunately makes it impossible to review it here, but it will be reviewed elsewhere. At the same time it is most contradictory, apparently because the following facts have not been taken into consideration by some of the workers:

1. Vitamins are food factors; therefore thyroid hormone, the chief function of which is to increase the oxidation processes in the organism, increases the metabolism of the vitamins in a similar way to that, for example, of proteins, fats, and carbohydrates. Thus depletion of *vitamin A* in the organism of animals by thyroid hormone administration has been found by Abelin (1933), Parhon and Werner (1935), Sure and Buchanan (1937), and Mlinko (1938); a similar condition in hyperthyroid patients was indicated by Wohl and Feldman (1938). With regard to *vitamin B*, of especial importance are experiments by Himwich, Goldfarb, and Cowgill (1932), Hendricks (1933), Cowgill and Palmieri (1933), Cowgill (1934), and Drill (1938), who showed that the requirement of vitamin B of an organism per unit of mass is proportional to the metabolism of that mass, and that thyroid hormone therefore greatly increases this requirement. The depletion of *vitamin C* from the animal organism by thyroxine has been recorded by Demole and Ippen (1935), Plaut and Bülow (1935), Mosonyi (1935), Nespor (1936), Sure and Theis (1938), and Thaddea (1938). Increase of metabolism due to any cause accordingly requires increased administration of vitamins: e.g., in the case of muscular work, Cowgill (1934) found this for vitamin B and Hamel (1937) for vitamin C.

2. Therefore when even non-toxic doses of thyroid hormone are given or mild hyperthyroidism is present without a corresponding increase in vitamin administration, a relative vitamin deficiency might develop with more or less pronounced symptoms of anorexia, partial starvation, and loss of body weight.

3. For these reasons it is difficult to draw definite conclusions as to the antagonistic effects of thyroid hormone and vitamins from the experiments of several previous workers who used, often deliberately, a diet deficient in, or containing only a minimal normal amount of, the vitamin investigated, or used toxic doses of thyroid hormone.

The effects produced by any substance differ greatly according to whether toxic or non-toxic doses are used. In toxicosis, non-specific, mostly destructive, changes occur which obscure the specific changes. This is true both for thyroxine and for vitamins.

Technique

Non-toxic Experiments.—All these facts were taken into consideration when planning our experiments (see Tables I and II), performed on rats kept on our usual diet. This diet is rich enough in all vitamins to ensure (this appears to be the best test) excellent breeding results. We have chosen as criteria for judgment of antagonism or co-operative activity the changes in body weight and weights of most of the organs, fat deposition, and histological structure of thyroid gland. We have used non-toxic doses both of thyroid hormone and of vitamins, but in the case of vitamins, except with vitamin D, they were much above the normal requirement, while with thyroid hormone they were large enough to produce specific and typical changes (Korenchevsky and Hall, 1941).

Experiments were performed on 121 male rats for investigation of the effects of vitamins B and C, and on 66 female rats for investigation of vitamins A and D. The final age of the rats averaged 150 days. Each experiment was repeated twice. Although the doses and, in the case of vitamin B complex, the numbers of vitamins B used were somewhat different in the first and second experiments, the results were similar. The data from both experiments were therefore pooled, and average figures only are given in Tables I and II.

TABLE I.—*Effects of Non-toxic Hypervitaminosis A and D on the Means of Body Weight, Fat Deposition, and Actual Weights of Organs in Normal Female Rats and in Rats treated with Non-toxic Doses of Thyroid Hormones**

Organs	Co−V	Co+V	Thy−V	Thy+V

Gain in body weight, g.	52	51	43	38
No. of rats in group	16	16	16	18

* In this and the following table "Co−V" denotes the group of control rats receiving no additional substances; "Co+V" the group of rats receiving an extra amount of vitamins; "Thy−V" the group of rats receiving thyroid hormone alone; "Thy+V" the group of rats receiving simultaneously thyroid hormone and an extra amount of vitamins.

No changes in weight of uterus, vagina, thyroid, hypophysis, and brain were obtained in this experiment.

The doses used were as follows: In the first experiment 85 mg. of desiccated thyroid in the form of a sweetened emulsion was given orally by pipette 3 times a week; and 0.6 mg. of thyroxine was injected subcutaneously twice a week. In the second experiment desiccated thyroid only was given, but in a larger dose—180 mg. for the first month of the experiment and 280 mg. for the rest of the experiment—6 times a week. Vitamins A and D were given orally in the form of halibut-liver oil diluted with cod-liver oil, the daily dose (4 drops by pipette) containing 1,300 I.U. of vitamin A and 70 I.U. of vitamin D, 6 times a week in both experiments.

* No changes in weight of testes, penis, thyroid, hypophysis, and brain were obtained.

In the first experiment vitamins B were given orally in the form of a sweetened emulsion 6 times a week, the daily dose being: aneurin 0.22 to 0.5 mg., riboflavin 0.22 to 0.5 mg., nicotinic acid 2.2 to 5 mg. In the second experiment the same vitamins B and doses were given by mouth, with in addition subcutaneous injections 6 times a week, each dose containing 0.4 to 0.5 mg. aneurin, 0.5 mg. pyridoxine, and 1.5 to 2 mg. calcium pantothenate. In both experiments 20 mg. of vitamin C was given orally by pipette 3 to 6 times a week, and in addition 25 to 40 mg. was injected subcutaneously 6 times a week. The duration of the first series of experiments was 53 days and of the second 47 days.

Toxic Experiment.—An additional experiment was performed on 18 male rats (Table III) in order to discover in particular whether different effects are produced by thyroid hormone and vitamins B when (as in most experiments of previous workers) toxic doses of thyroid hormone are given to animals fed on a diet deficient in or containing a minimal normal amount of vitamins.

The diet was the same as that used in the non-toxic experiments but made considerably poorer in vitamin B complex by the exclusion of yeast and wheat germ, which were replaced by bread, and the substitution of rolled oats only for the grain mixture. One mg. of thyroxine was injected daily for 13 days, the rats being killed on the fourteenth day. To the rats of group 3 (Table III) the same vitamins B were given as in our second experiment: aneurin, riboflavin, and nicotinic acid by mouth, supplemented by subcutaneous injections of aneurin, pyridoxine, and calcium pantothenate. The doses were also the same, except the dose of aneurin injected, which was raised to 1 mg. The rats of group 4 received in addition yeast and wheat germ (incorporated in the diet in the same proportions as in our original diet) either alone or plus the same amount of crystalline vitamins B as in group 3.

All changes obtained were statistically analysed by one of us (B. Clapham) by means of Fisher's t-test. Unless they are mentioned as being "statistically not significant," all the results obtained were found to be statistically significant.

Experimental Hyperthyroidism

Non-toxic Hyperthyroidism.—The following changes, all statistically significant, were observed after administration of non-toxic doses of thyroid hormone (compare, in Table I, group 3 with group 1, and in Table II, groups 3 and 7 with groups 1 and 5): decreased gain in body weight and fat deposition, hypertrophy of adrenals, liver, kidneys, spleen, heart, and preputial glands in both sexes; hypertrophy of ovaries in females; and small decrease of seminal vesicles and prostate in males. Histological changes in the thyroids demonstrated a strong depressing effect on their function (flattened epithelium, accumulation of solid colloid in enlarged follicles). A preliminary histological examination of ovaries, adrenals, liver, kidneys, spleen, and heart confirmed our conclusion suggested by the increase in weight of these organs—namely, that thyroid hormone has a stimulating hypertrophying effect on them. A detailed microscopical investigation, however, might show new facts; it will be described elsewhere. Thus non-toxic doses of thyroid hormone simultaneously increased both anabolism (shown by hypertrophy of several of the organs) and katabolism (decreased gain in body weight and fat deposition), the anabolic processes prevailing over the katabolic. Although the treated animals were thinner than the controls they had the appearance of perfectly healthy animals.

Thyroid hormone therefore has hepatotrophic, nephrotrophic, and cardiotrophic properties similar to those of androgenic hormones (Korenchevsky and Ross, 1940; Korenchevsky, Hall, Burbank, and Cohen, 1941), but its effect on adrenals appears to be different from that of androgens (Hall and Korenchevsky, 1938). The effect of simultaneous administration of thyroid and androgenic hormones should be investigated with the object of determining whether they might be used for therapeutical purposes in suitable diseases of liver, kidneys, and heart. Epstein (1922, p. 186), for example, obtained "striking" favourable results after the treatment of chronic parenchymatous nephrosis with thyroid hormone.

Toxic Hyperthyroidism.—The administration of toxic doses of thyroid hormone was followed by an atypical reaction (compare group 2 with group 1, Table III): loss of body weight, much greater atrophy of seminal vesicles and prostate and considerably less hypertrophy of kidneys, atrophy instead of hypertrophy of liver and spleen, decrease of testes, and pronounced involution of thymus. At the same time all the animals became weak and emaciated; their fur became dull, rough, and dirty; most rats suffered from diarrhoea and began to lose weight; and some died from thyrotoxicosis before the end of the experiment. Histologically the same depression of thyroid function was observed as with non-toxic doses. Thus in general, instead of the predominant typical anabolic and hypertrophic reaction (still preserved only in adrenals and heart), with toxic doses katabolic and atrophic changes prevailed, resulting in some cases in the death of the animals.

Effect of Hypervitaminosis

The administration of the extra amounts of vitamins produced no considerable effects, if any (compare group 2 with group 1, Table I; and groups 2 and 6 with groups 1 and 5, Table II). Hypervitaminosis B and C (Table II) produced in male rats a small, consistent, but statistically not significant increase of seminal vesicles, liver, and fat deposition. Vitamin B also produced greater gain in body weight and improvement in external appearance and behaviour (the rats appeared to be more lively and, when handled, felt firmer and stronger, and had thicker and more glossy fur than the control groups "Co−V"). Histologically no definite effect of these doses of vitamins could be found on the structure of the thyroid gland, except perhaps a slightly depressing effect of halibut and cod-liver oils. This could easily be explained by the extra amount of iodine given in these oils (Mellanby, 1934; Sampson and Korenchevsky, 1932).

Effect of Hypervitaminosis on Hyperthyroidism

The effect of hypervitaminosis on non-toxic hyperthyroidism (group 4 in Table I, and groups 4 and 8 in Table II) was different from that on toxic hyperthyroidism (groups 3 and 4, Table III). In rats kept on our *normal diet and receiving non-toxic* doses of thyroid hormone, vitamins A and D (in the doses given) did not at all affect the specific reaction of organs and tissues to this hormone, while vitamins B and C produced a slight decrease in the hypertrophy of liver and kidneys. In rats kept on a *minimal normal* amount of vitamins B (Table III) and injected with *toxic* doses of thyroxine, the simultaneous administration of extra amounts of vitamins B was followed by a gain instead of a loss in body weight and the partial restoration of specific anabolic changes instead of a pathological (atrophic and almost exclusively katabolic) reaction of the organs to thyroid hormone. In such animals the atrophic changes were decreased in seminal vesicles, prostate, and liver and replaced by hypertrophy in spleen, while in kidneys hypertrophy became more pronounced. The fact that some typical reactions to thyroxine were not prevented in such animals indicates that in vitamin-treated rats suffering from thyrotoxicosis all the improvements described both by previous workers and by ourselves (including gain instead of loss in body weight) could be explained by the making good of the relative vitamin deficiency produced by, and complicating, the thyrotoxic effects. Histologically the thyroid glands were in the same resting condition as in the rats treated with thyroid hormone alone.

The results of our experiments therefore indicate that for the investigation of antagonistic effects neither toxic doses of thyroxine, which greatly raise the vitamin requirements and produce non-specific changes, nor diets with inadequate levels of vitamin content appear to be suitable.

Conclusions

In the therapeutical application of thyroid hormone its katabolic properties in raising metabolism and especially in reducing body fat are often taken most into consideration.

The results of our experiments (as judged by changes in weights and histological structure of organs) and those of some previous workers emphasize that thyroid hormone also possesses anabolic properties, which can lead to better development of such vital organs as liver, kidneys, spleen, heart, and adrenals in both sexes, and ovaries in females.

As shown especially in our experiments on females, it is possible, using moderate doses of thyroid hormone, to reduce the body fat to about one-fifth without affecting appreciably the gain in body weight, and at the same time preserving the stimulating anabolic effects of this hormone on the development of the vital organs mentioned above.

Thus from small or moderate doses of thyroid hormone favourable therapeutical results can be expected, but when large doses are given the useful effects disappear and the hormone becomes atypically toxic and dangerous.

The useful effects of thyroid hormone cannot be normally and fully operative, unless liberal amounts of vitamins are given simultaneously, because of the increased requirements in vitamins which arise during conditions accompanied by increased metabolism (such as those produced by thyroid hormone).

Therefore the best possible therapeutical results can be expected from simultaneous administration of thyroid hormone with extra amounts of vitamins.

Since both thyroid hormone and male sex hormones possess hepato-, nephro-, and cardiotrophic properties, and thyroid hormone also produces ovario-, spleno-, and adrenotrophic effects, the possibility of therapeutical application of thyroid hormone in cautious doses with vitamins, or together with sex hormones, should be investigated in some suitable diseases of liver, kidneys, and heart, or when an increased activity of ovaries, adrenals, or spleen is desirable.

The results of our experiments and those of some previous workers do not suggest, as has been stated by certain authors, any direct antagonistic effects of vitamins on thyroid hormone; but the data indicate that some beneficial results of the administration of vitamins in some cases of experimental and clinical hyperthyroidism were probably due chiefly to removal of the relative vitamin deficiency present in these cases.

Grants from the Medical Research Council and the Lister Institute have enabled us to carry out this work, and to them we offer our thanks. We are also grateful to the Ella Sachs Plotz Foundation for a grant from which some of the technical expenses were met. We are indebted to Messrs. Roche Products Ltd. for the generous supply of vitamins, and to Messrs. Parke, Davis and Co. for the liberal supply of desiccated thyroid powder.

THE INCREASING IMPORTANCE OF ENDOCRINOLOGY IN GENERAL MEDICINE*

BY

S. L. SIMPSON, M.D., F.R.C.P.

Physician, Willesden General Hospital, with charge of Diabetic Clinic; Physician, Princess Louise Kensington Hospital for Children; Consulting Physician, Soho Hospital for Women

In this address I hope to be able to indicate clearly that the "increasing importance of endocrinology in general medicine" is a reality and is of interest to the physician, surgeon, and gynaecologist, and therefore to the general practitioner.

Adrenal–Pituitary Disorders

Cushing's Syndrome.—I shall first consider a syndrome which has been brought into prominence in the last decade by the observation of Harvey Cushing (1932), but which had already been recognized and described as the "fat bearded diabetic woman" by Achard and Thiers. The eponymous title was suggested by Parkes Weber, who had himself previously given a magnificent clinical description of the disorder. Cushing's invaluable contribution was to draw attention to the possibility of a basophil adenoma of the anterior pituitary being a primary cause, comparable to the eosinophil adenoma of acromegaly. It is now recognized that other primary causes exist—namely, tumours of the adrenal cortex, of the ovary, and of the thymus

---

* Delivered as the Annual Oration to the Leeds Jewish Hospital Medical Society, Nov. 29, 1942.

—but Crooke (1935) has shown that a constant change in all these pathological entities is hyalinization of the basophil cells of the anterior pituitary. Cushing described his syndrome as follows:

> "(1) A rapidly acquired, peculiarly disposed, and usually painful adiposity (in one instance representing a 40% gain in weight), confined to the face, neck, and trunk, the extremities being spared; (2) a tendency to become round-shouldered (kyphotic), even to the point of measurable loss of height associated with lumbo-spinal pains; (3) a sexual dystrophy shown by early amenorrhoea in the females and ultimate impotence in the males; (4) an alteration in normal hirsuties shown by a tendency to hypertrichosis of face and trunk in all the females as well as the pre-adolescent males and possibly the reverse in adult males; (5) a dusky or plethoric appearance of the skin with purplish lineae atrophicae; (6) vascular hypertension; (7) a tendency to erythraemia; (8) variable backaches, abdominal pains, fatigability, and ultimate extreme weakness."

This description gives an indication of the protean manifestations of an endocrinopathy, but it is more important to realize that a presenting symptom may overshadow the rest of the picture. Thus the disorder may be diagnosed as essential hypertension, nephritis, malignant nephrosclerosis, cerebral tumour, diabetes mellitus, polycythaemia, idiopathic adiposity, or sterility in the female or impotence in the male. It is also important to remember that an idiopathic adiposity may be the precursor of the complete syndrome, which may manifest itself only at the climacteric or in the course of a pregnancy. Not all patients developing Cushing's syndrome are sterile or without menstrual bleeding, although the latter tends to be scanty (Simpson, 1936).

The differentiation of the pathological varieties of Cushing's syndrome is helped by biological assay, and in 1934 and 1936 my colleagues and I recorded a high androgen excretion in virilism. I suggested the origin of androgens from the adrenal cortex and the significance of urinary 24-hourly values above 300 international units as indicating an adrenal cortical tumour. Work in this field was fruitfully developed by R. K. Callow (1938a, 1938b), with whom I collaborated on the clinical side over a number of years, especially in the demonstration of urinary androgens after bilateral ovariectomy.

Phaeochromocytoma of Adrenal Medulla.—A phaeochromocytomatous tumour of the adrenal medulla consists of adrenaline-secreting chromaffin cells, which discharge into the blood paroxysmally, though possibly also in constant small quantities. Hypertension, with periodic exacerbations to very high levels—e.g., over 300 mm. Hg, with the diastolic pressure rising to a relatively smaller extent—is the major manifestation. These vasomotor crises are due to a discharge of adrenaline into the blood stream; and other features are pallor, coldness and cyanosis of the extremities, profuse perspiration, trembling, agonizing headaches, painful constricting sensations in the chest with difficulty in breathing, angina-like pains, cramps of the calf muscles, mydriasis, albuminuria, and pyrexia. Ischaemic nephritis may also occur. The presenting features of the disorder, however, may be attacks of cyanosis, coughing and blood-tinged sputum, and pulmonary oedema; blurred vision, papilloedema, retinal haemorrhages, exophthalmos, mydriasis, and cephalalgia; epigastric pain, nausea and vomiting; an enlarged thyroid, with tachycardia; albuminuria and hypertension; attacks of coma due to hypertensive encephalopathy; hypersensitivity to heat associated with a considerably raised basal metabolic rate. The following mistaken diagnoses have been made: neurosis, neurocirculatory asthenia, thyrotoxicosis, diabetes mellitus (but severe diabetes mellitus may coexist), essential hypertension, malignant nephrosclerosis, pulmonary oedema, cerebral tumour, acute abdomen, and angina. The chief cause of such mistaken or incomplete diagnoses is the failure to realize that such a syndrome exists.

Sexual Precocity.—It is well known that sexual precocity may be associated with neoplasms of the endocrine glands, especially of the adrenals. It is less well known that the primary lesion may be a cerebral neoplasm in the neighbourhood of the third ventricle, producing its effects via the hypothalamic-pituitary mechanism, and it is probable that the classical sexual precocity associated with pineal tumours is also produced through this mechanism and not through an absence or excess of pineal gland secretion. There are sometimes, although by no means always, interesting points of clinical differentiation, but the essential point I wish to make is the overlapping of the endocrinological and neurological field. We have a similar overlapping, not well recognized, in the condition of gigantism, which does not necessarily present itself as a pathological entity, but as a variety of normality. Thus recently a mother brought her daughter of 14 to see me because the girl was easily tired and she thought it was due to her growing too rapidly. Examination of the fundi did not show the optic atrophy associated with a pituitary tumour, but the papilloedema of increased intracranial pressure, the latter confirmed by radiographs. The probability is that we are dealing with a third-ventricle tumour, and ventriculograms are being taken for further indications.

Addison's Disease.—This disorder is well known as a clinical entity, and interest has been intensified by the discovery of a potent cortical extract. But the protean manifestations of the disorder, and the fact that it is comparatively rare, lead to mistaken diagnoses, especially in fair people in whom pigmentation is minimal or absent, or in whom it is identical with that of leucodermia. Addison described one such case, and I have had three cases under my care, one ending fatally and showing atrophy of the adrenals at necropsy. I have seen a case of Addison's disease for the first time at necropsy, after the patient had been operated on because of an erroneous diagnosis of perforated gastric ulcer, the original disorder being quite unsuspected, although typical pigmentation in moderate degree was visible at the necropsy. Severe abdominal pain may be a feature of Addison's disease. Asthenia and psychoneurosis are other erroneous diagnoses met with. On the other hand, the label of Addison's disease may be incorrectly given. Thus I have had cases labelled Addison's disease in which the diagnosis was pregnancy with functional vomiting, carcinomatosis, pellagra, anorexia nervosa, and chronic arsenical poisoning. The Cutler or Kepler test of sodium and chlorine concentration in the blood and urine is valuable not so much for confirming Addison's disease as for excluding this diagnosis in a variety of disorders in which it may be suspected, often with some reason.

Simmonds's Cachexia.—The characteristics of this disorder, due to insufficiency of anterior pituitary function, are anorexia, wasting, weakness, hypotension, bradycardia, and loss of primary and secondary sexual qualities. The disorder as a complete syndrome is a rarity, but as an incomplete syndrome following pregnancy, especially with haemorrhage or infection at parturition, it is in my experience by no means uncommon, and is often missed entirely or mistaken for myxoedema. On the other hand, the condition of anorexia nervosa, which is primarily a psychoneurosis but secondarily a vitamin-deficiency and hormone-deficiency disorder, is often mistaken for Simmonds's cachexia. Clinically, the restless energy, the persistence of sexual hair, and a generalized downy growth of hair characterize anorexia nervosa, and further differentiation may be obtainable from urinary androgen assay and insulin-sensitivity curves.

Diabetes Mellitus

I refer only briefly to this condition because it is familiar to all of you, but it illustrates quite forcibly the thesis that endocrine disorders may present themselves as non-endocrine disorders in various branches of medicine. Thus it is now platitudinous to point out that the diabetic may first appear as suffering from boils, carbuncles, general pruritus, pruritus vulvae, dermatitis, xanthomatosis, neuritis, endarteritis with ulceration and gangrene of an extremity, cataract, retinitis, amenorrhoea, impotence, or infantilism, and such widespread manifestations are equally true of many other endocrinopathies.

I would suggest here that diabetes should not be arbitrarily excluded from the field of endocrinology because of the mathematical calculation of dietary values, and that those who have specialized in the field of diabetes could very appropriately extend their interests to the whole field of endocrinology. Not only has Young (1937) stirred the experimental and clinical world by the production of permanent pancreatic diabetes by injections of a pituitary diabetogenic hormone, but it has also been shown (Lukens and Dohan, 1942) that the development of this pancreatic diabetes can be prevented by insulin or diet, and can even be abolished or cured in the early stages. There is little doubt that this mechanism of producing a type of diabetes operates clinically in man, and it is well known that diabetes may complicate acromegaly, Cushing's syndrome, thyrotoxicosis, and other endocrine disorders. It is less well known that it may coexist with Addison's disease (Simpson, 1932), or that the latter may be superimposed upon pre-existing diabetes. I have seen two such cases, one through the courtesy of Dr. R. D. Lawrence. A small number are recorded in the literature (McCullagh, 1942), and the involvement of the suprarenals may remain unsuspected. Essentially the diabetic tolerance improves and the insulin dosage is progressively lowered, but clinically the patients get thinner and weaker. Pigmentation may not be conspicuous. A study of sodium chloride metabolism confirms the diagnosis.

The Gonads

The field of gynaecology and obstetrics is saturated with, and I think overwhelmed by, the vast amount of animal experimental endocrinology and therapeutic indications deduced therefrom. Several books have appeared on the endocrinological aspects of, or endocrine therapy in, gynaecology. Unfortunately species differences often invalidate application of the results of animal experiments to man; and, on the whole, endocrine therapy in this field has been tantalizingly promising but somewhat disappointing. Potentially it remains a very fruitful source of further study. Neither should one limit attention to the more obviously pathological—such as the endocrine concomitants—or aetiological factors in eclampsia. Physiological aberrants are equally important. Thus the increasing adiposity that follows each pregnancy in those with an unstable endocrine constitution is almost certainly associated with failure of involution of the physiological pituitary and adrenal hyperplasia, and the persistence of adrenal androgen secretion is often indicated by an accompanying mild but definite hirsutism.

The brilliant results of oestrogen therapy in the vasomotor and psychoneurotic disturbances of the climacteric are too well known to bear repetition, but it is not generally realized that such disturbances may persist for ten or more years after the menopause or may return after a long interval of freedom, or may supervene for the first time ten years after the menopause, just as they may occur in the late forties in a woman who has been completely ovariectomized in the second or third decade of life.

In the male the treatment of sterility by gonadotrophic hormone or small doses of androgens is far from satisfactory, but the treatment of hypogonadism in the surgical castrate or eunuchoid is dramatic. Also, excellent physical and mental improvement has occurred in a group of cases showing juvenilism in the presence of apparently normal genital function. Impotence due to organic hypogonadism always responds to androgenic therapy, but psychological impotence calls for psychological treatment.

Parathyroids

Hyperparathyroidism, due usually to an adenoma of one of the parathyroid glands, is primarily an endocrine disorder, but its manifestations are in the main skeletal, the general decalcification and rarefaction of bones resulting in bony deformities, spontaneous fractures, and variable bone pains. Previous to the discovery of the function of the parathyroids and knowledge of the high serum calcium, low serum phosphorus, and negative calcium balance in this condition, the disorder was often confused with osteitis deformans and more localized forms of rarefying osteitis. I have recently seen a case in a woman of 40 who first had a localized bony swelling of the tibia removed, the histological report being osteoclastoma. It was only some months later that the underlying condition was recognized, and a parathyroid tumour sought for, found, and removed. This patient also had multiple renal calculi (calcium deposits)—which reminds one that these patients may first present themselves to the urogenital surgeon with renal colic or haematuria; or, if the calcium deposition is generalized (calcinosis), there may be severe renal insufficiency and uraemia. In such cases the inadequate excretion of phosphorus blurs the chemical picture.

Hypoparathyroidism appears to be more common in Denmark than in this country. It may be due to atrophy or degeneration of the parathyroids or may follow thyroidectomy for thyrotoxicosis in a small percentage of cases, interference with blood supply being apparently at least as important as inadvertent removal of parathyroid glands. In addition to the characteristic tetany (associated with a low serum calcium and high serum phosphorus) there may be various cerebral and mental disturbances, with epileptiform convulsions, changes in character, hallucinations, and dementia. It is known that patients have been treated as idiopathic epileptics for years (as has been the case with hypoglycaemic attacks resulting from pancreatic islet tumours). Hypoparathyroidism may also present itself in the first place as a trophic disturbance of the skin, hair, nails, teeth, or eye lenses (cataract). Thinning or loss of hair, impetigo herpetiformis, acrodermatitis continua, psoriasis pustulosa, and various ill-defined eczematous lesions have been found associated with hypoparathyroidism, and have apparently responded to calcium and calciferol therapy. Lachmann (1941) states that migraine, cardiac pain with palpitations, and gastro-intestinal spasm severe enough to lead to laparotomy may be presenting features in unsuspected hypoparathyroidism.

Thyroid Gland

The diagnosis of thyrotoxicosis, primary or secondary, is relatively easy, yet it is surprising how often the condition is missed, even when the manifestations are characteristic, and especially when the presenting feature is not obviously endocrine. The cardiologist's awareness of thyrotoxicosis as one cause of tachycardia, auricular fibrillation, or angina-like pain is now taken for granted, and more recently attention has been drawn to the possibility of a small group among hypertensive cases being thyrotoxic in origin. It is perhaps less well realized that anginal pains, cardiac insufficiency, and electrocardiographic changes may have myxoedema as their background. The pulse is usually slow in myxoedema, but may be rapid in the presence of cardiac insufficiency. The capillaries also show characteristic narrowing and absence of tortuosity.

Gastro-intestinal symptoms may be severe in thyrotoxicosis, and I have seen a necropsy on one patient who was operated on for a "query perforated gastric ulcer," the diagnosis at operation having been changed to acute pancreatitis, the pancreas being very congested. I have also seen a necropsy on a patient who was admitted in semi-coma with the diagnosis of "query intracranial haemorrhage, query concussion, with cerebral irritability," when the patient was really in the terminal stages of a thyrotoxicosis crisis. I have seen several cases of "idiopathic wasting, query malignancy" in older people with unsuspected secondary thyrotoxicosis who recovered a few stone in weight following thyroidectomy.

Asthenia is commonly present in thyrotoxicosis, and rarely myasthenia gravis may coexist, but thyrotoxicosis may be wrongly diagnosed as myasthenia gravis or progressive muscular atrophy. Neurocirculatory asthenia may be associated with enlargement of the thyroid gland, but it is coincidental, and an erroneous diagnosis of thyrotoxicosis has led to a useless thyroidectomy.

Psychoneuroses and the Psychoses

Endocrinopathies are more often associated with psychoneuroses than with psychoses, but the latter may coexist with, or be precipitated by, endocrine disorders—e.g., manic-depressive disorders, paranoia, delusional insanity in thyrotoxicosis, myxoedema, chronic hypoparathyroidism, chronic hypoglycaemia, and the climacteric. Hemphill and Reiss (1940) recognize a type of involutional melancholia associated with adiposity and scanty or absent menstruation which they claim responds to oestrogen therapy; and a hypo-ovarian–hypo-adrenal type which is said to respond to corticotrophic hormone. A cautious approach to the problem is called for, and a critical evaluation of cause and effect is essential, but it is interesting to note that many years ago Mott drew attention to the degeneration of the testes in dementia praecox.

It is my opinion that all endocrinopathies, constitutional or more obviously pathological, influence behaviour pattern, and that the association of mild or severe psychoneuroses with untreated endocrinopathies is very frequent. This is obvious with thyrotoxicosis and the climacteric, for example, but I have seen a transformation of personality follow adequately treated Addison's disease, eunuchoidism, and even hyperparathyroidism. The important point is that a group of psychoneuroses and psychoses coming to the psychiatrist in the first case may have an underlying endocrinopathy as an aetiological factor.

Endocrines and Ophthalmology

In 1938 Sir Walter Langdon-Brown gave a lecture to the Oxford Ophthalmological Congress reviewing the ocular manifestations of endocrinopathies as they present themselves to the ophthalmologist. Parathyroid, pineal, pituitary, thyroid, adrenal medullary, gonad, and pancreatic disorders may all show ophthalmological signs, and these may for a time be the presenting feature.

Endocrines and Cancer

Experiments in small animals, such as mice, indicate that oestrogens in large doses over long periods may induce neoplastic growth in genital and other organs. Thus Allen (1942) records cancer of cervix uteri (mice), uterine fibromyomas (guinea-pigs), mammary cancer (mice), interstitial cell tumours of the testis (mice), adenomatous tumours of the pituitary (rats and mice), tumours of the suprarenal cortex (mice), and osteogenetic transformations of bones including tumours (mice). Such neoplastic changes are not found in monkeys, and there is no clinical evidence of the endocrines being responsible for malignant changes in the genital or other organs in man.

Endocrine Therapeutics in Non-endocrine Disorders

Hormones have been used with success in a number of non-endocrine disorders. Thus insulin is anabolic in some thin people, and recently Sargant (1942) has found it useful in a group of neurotics who have lost much weight and have broken down after a long period of stress, showing "a peculiar mixture of anxiety, hysterical, and reactive depressive symptoms." Insulin has also been used in the vomiting of pregnancy and in thyrotoxicosis. Insulin-shock therapy is apparently more beneficial than electric-shock therapy in early schizophrenia. It is claimed that cortical extract has proved of value in surgical shock and shock from burns, the blood chemistry in both instances having some similarity with that of Addison's disease. Apparently the corticosterone carbohydrate influencing factor is more important than the desoxycorticosterone factor. In infections the adrenal cortex loses lipoid and undergoes congestion and degeneration. Cortin has therefore been advocated for the acute stages of a variety of infections, especially malignant diphtheria, and for post-infection debility. It is also said to be of value in meningococcal septicaemia of infants, as is illustrated in the Waterhouse-Friderichsen syndrome. Oestradiol appears to be of value in a group of menopausal rheumatoid arthritics. Testosterone I have found of value (Simpson, 1938) for its anabolic nitrogen-retaining effect in hyperthyroidism associated with much wasting. It has also been used for menorrhagia and mastitis. Both testosterone and stilboestrol are effective in suppressing lactation. Adrenaline is of course specific in asthma. Pitressin has been used for chronic pyelitis, and in obstetrics.

Conclusions

I think we must conclude from the above review that the manifestations of endocrine diseases extend throughout the whole domain of medicine, including in that term surgery and gynaecology and the various "special" branches of medicine; that endocrine disorders do not necessarily appear as complete syndromes; and that unless an awareness of the possibilities is present they may remain unrecognized as endocrinopathies when the presenting feature is not obviously endocrine. In the opposite direction one sees a tendency to ascribe the origin of obscure chronic disease, especially of a functional character, to endocrine disorders which are not really present, and the necessity for a knowledge of existing methods of differentiation and the development of more specific chemical, metabolic, and biological tests.

Endocrinology, however, viewed from any angle, is no longer merely a lusty infant. It has grown to maturity, and is at least as well founded on scientific data as many other older accepted specialties. I doubt whether it would gain from the founding of a special hospital for its study—rather would it tend to flourish as special centres or clinics in large hospitals, remembering that such centres for accumulating clinical material from large areas are essential for progress in this field. Such centres or clinics, however, must not be auxiliary adjuncts in the charge of assistants, created merely to give an air of modernity or progress. Endocrinology is one of the most difficult specialties. Its practice, and even more so its teaching, require wide general clinical experience and judgment, as well as personal experience and continuous familiarity with the enormous and ever-widening field of experimental research and a specialized knowledge of endocrinopathies, which can only be obtained by those who have had special facilities and opportunities for their study. An endocrine clinic should be an important integral part of a hospital, and should serve as a model for modern methods of investigation, research, and therapy in disease.

USE OF AMPHETAMINAE SULPHAS IN FACILITATING ELECTRICALLY INDUCED CONVULSIONS

BY

K. C. BAILEY, M.D., D.P.M.

Deputy Medical Superintendent, St. James Hospital, Portsmouth

The use of electricity for inducing convulsions in the treatment of mental disorders has revealed a significant factor in connexion with the electrical stimulus. The electrical convulsion threshold has been found to vary, so that not only do successive applications of electricity require increasing strengths of current, but also there is a wide variation in the initial effective amount necessary. In some patients, more noticeably those suffering from certain types of disorder, a very high threshold either obtains from the outset or rapidly develops. In view of the possibility that electricity, particularly in high strengths, may not be altogether harmless, it seems desirable to discover methods by which the electrical convulsion threshold may be lowered. This to some extent may be achieved by increasing the interval between successive treatments, but at least in the cases exhibiting a high initial threshold recourse cannot be had to this method. Moreover, the period of the treatment would be much prolonged. Other ways of achieving the same objective are suggested by the fact that certain drugs have a stimulating effect on the cerebral cortex, and, owing to the results obtained with amphetaminae sulphas (benzedrine sulphate), experiment in the use of this drug was thought likely to be effective, and was therefore undertaken. Before the results of this procedure are examined it is profitable to consider the theoretical basis of this ascertained variation in the electrical convulsion threshold.

So complex has the nomenclature in psychiatry become, and so difficult is it to fit cases into definite disease entities, that it is often more useful to consider symptom-complexes. Particularly is this so in relation to therapeutic measures.

Variations in Cerebral Activity in Psychotic Disorders

Certain types of psychotic disorders exhibit the symptom of diminution of motor activity. This occurs particularly in depression and in schizophrenia. It may be of any degree from lassitude and a disinclination to do anything to apathy and even stupor. When such a prominent feature presents itself, it is pertinent to seek a reason for it, particularly when it occurs in such widely different types of mental disorders as manic-depressive and schizophrenic psychoses. In the former there is a true depression with often suicidal tendencies; in the latter there is an absence of emotional tone, with a consequent apathy. Both of these lead to a diminution of activity, which in an extreme degree is manifested by stupor. A consideration of the stupor reveals two different types—that occurring in depression being more often of the anergic type, in which there is a loss of muscular tone and in which mental processes such as perception, memory, and ideation appear to be in abeyance; whereas that occurring in schizophrenia is usually of the resistive katatonic type. Here there is a retention or even an increase of muscular tone, causing the posture of the patient to remain as arranged, undetermined by gravity, and the mental processes are not in abeyance, so that mannerisms and stereotypy occur and outbursts of excitement and impulsive behaviour interrupt the stupor. Apparently in the anergic stupor the cerebral activity is lowered so that there is a diminution of sensory stimuli to, and a reduction of more impulses from, the brain, with an associated paucity or lack of motor function. On the other hand, in the stupor associated with schizophrenia there is a retention of the muscular tone and cerebral activity as shown by mannerisms, stereotypy, and impulsive behaviour. Thus the mechanism of the two conditions appears to be entirely different—that associated with depression being due to a reduction of cerebral activity, and that occurring in schizophrenia being due not to a reduction of cerebral activity but to failure of integrity.

Causes of Lowered Cerebral Activity in Depression

From these observations it is possible to conjecture about the likely causes of this lowered cerebral activity which occurs in cases of depression. One such view has already been advanced—namely, that it is due to inhibition of cerebral function. Thus Pavlov (1941), who attempted to apply his findings in animal experiments to mental disorders, considered that in depression there was a state of positive inhibition, which with advancing years ceased to be effective, so that the patients with depression and diminished motor activity in earlier life became excitable and unrestrained in their behaviour when old age overtook them.

This supposition that cerebral activity is diminished in these cases of depression appears reasonable, and it was hoped that, with the induction of fits by the electrical method of Cerletti and Bini (1938), the measurement of the resistance of the head preparatory to applying the shock current would be an indication of the cerebral resistance and inhibition. This, then, would be not only a useful guide to the effective amount of current required to produce a fit, but an index to the degree of cerebral inhibition in different mental states. Unfortunately this hope was not realized, and, although the factors responsible for this head resistance are not yet completely understood, enough data are available to connect it with changes in the skin and underlying structures. Thus Krause (1936) found that the resistance of impedance of the head depends on the skin, muscle, and periosteum, and that no difference occurred when the brain was replaced by a wet sponge. That the skin is the most important of these factors is the opinion of McGregor (1941) and Walter (1942), which is supported by the fact that the resistance is appreciably lower in hypoglycaemic states, when there is excessive sweating, than when the skin is dry. Atmospheric conditions also appear to affect the resistance, as, of course, does the degree of contact of the electrodes. Thus the measurement of the head resistance is no measure of the resistance of the brain, and certainly the apparatus supplied on the Solus machine is inadequate for this purpose. Hence any hope of using the measure of the head resistance as a guide to the degree of cerebral resistance, and therefore of inhibition, was not possible. Hemphill and Walter (1941) experienced the same difficulty when assessing the effect of epanutin in relation to electrically induced fits. They considered that the product of the voltage and the time of application of the current was a more useful index of cerebral resistance.

Shortly after the use of the electrical method to induce fits a great variation in the electrical convulsion threshold was found, and as in the case of the chemical methods, using cardiazol and triazol, a tolerance developed which raised the threshold. Besides this, however, different individuals varied widely, even in the initial threshold. The reason for this was not at first understood, but careful observation has shown it to depend upon two main factors—age, and the type of mental disorder. Naturally other factors may also operate to some extent, such as the difficulty, already mentioned, of the exact diagnosis, and the degree of contact of the electrodes. Nevertheless the following tables appear to be most suggestive.

TABLE I.—*Showing Variation of Average Electric Convulsion Threshold (expressed as the Product of Volts and Duration of Stimulus in Relation to Age, in 110 Patients, irrespective of Type of Mental Disorder*

Age Group :	16–20	21–25	26–30	31–35	36–40	41–45	46–50	51–55	56–60	61–65
Average V.×T. ..	18·3	20·2	23·2	23·4	24·4	26·9	28·9	30·9	34·5	42·
No. of patients ..	10	8	17	23	8	3	11	16	9	5

TABLE II.—*Showing Relation of Average Electric Convulsion Threshold to Type of Mental Disorder, and Average Age of Each Group*

Diagnosis:	Schizophrenia	Depression	Delusional	Obsessional	Toxic	Mental Defect	Mania
V.×T. ..	21.9	29·5	26·9	20·9	20·4	23.6	24
No. of cases	32	55	7	9	4	2	1
Average age of each group (years) ..	27·8	46	44	30·8	29·5	23	46

From Table I it is seen that the electric convulsion threshold increases with age. This suggests that an organic factor is operating. This is unaffected by sex, since the average threshold for females as compared with males is 26.9 to 24.7 in 110 cases, of which 75 were females and 35 were males. From Table II it is apparent that this threshold is increased in cases of depression as compared with other types of mental states, and that the average age for these cases of depression is the highest of any of the groups. This is significant, for it suggests that the increased threshold in cases of depression depends more upon age than on the actual mental state. It is still necessary, however, to attempt to discover why the threshold should increase with age and why depression should be more common in later life. One might surmise that organic changes occur with increasing age that make the cortex of the brain more resistant to stimuli, with correspondingly increased inhibition, and that when a certain degree of inhibition is present a state of depression occurs. This would explain the lack of adaptability and the dislike of change which occur in later life, and thus supports the theory advanced by Pavlov. Certainly the increased threshold is not due to the depression itself, for it does not occur in all cases, being more commonly found in the older depressed patients—between 40 and 60—as may be seen by comparing the average threshold in depressed patients younger than 40 with those over 40. It was 23.1 and 33 respectively. Further, if the raised threshold depended upon the depression, it should tend to become lower as improvement occurred. This was not found, and even if the condition of tolerance, which itself raises the threshold, tended to some extent to mask any lowering of the threshold due to the mental improvement, this latter must be extremely small or it would, at least, have compensated for the rise due to the tolerance. The increased electric convulsion threshold appears, therefore, to be brought about by changes in the cerebral cortex as a result of age, which at first are reversible but which later become irreversible, as seen by the lack of response to treatment in the more chronic cases.

Tests with Amphetaminae Sulphas

If, as has been suggested, the increased electric convulsion threshold is due to changes in the brain, they should be capable of modification by drugs known to act on the brain. It is now common knowledge that sedative drugs, such as the barbiturates, by depressing cortical activity, increase the electric convulsion threshold, as shown by Hemphill and Walter (1941) in the case of disodium diphenyl hydantoinate. It was therefore considered useful to test the effect of a cerebral stimulating drug on the electric convulsion threshold, and in view of the improvement that occurs from amphetaminae sulphas (benzedrine sulphate) alone in certain cases of depression, it was decided to employ this drug. Accordingly 5 mg. was given by mouth to each patient, to test their susceptibility, and thereafter 10 mg. was given one hour before the electrical treatment. The results in 6 patients are tabulated below:

Case I, aged 56

No. of T'ment:	1	2	3	4	5	6	7	8	9	10	11	12
Volts × Time ..	26	45	48	80	80	75	75	75	45	24	24	24
Milliamps of current passed ..	30	81	104	225	250	162·5	175	200	78	35	28	26
Amphet. sulph. in mg. ..									5	10	10	10

Case II, aged 42

No. of T'ment:	1–16	17	18	19	20	21	22	23	24	25	26
Volts × Time	26	39	26	45	45	45	45	30	30	45	45
Milliamps of current passed	30	93	32	78	87	87	93	38	35	99	78
Amphet. sulph. in mg. ..			5		10	10	10	10	10		

Case III, aged 54

No of T'ment :	1–4	5	6–8	9–19	20	21	22	23	24
Volts × Time .. .	26	52	48	52	36	26	26	26	26
Milliamps of current passed	29	104	112	122	82·5	35	33	35	34
Amphet. sulph. in mg. ..					5	10	10	10	10

Case IV, aged 62

Comments on Results

In Case I it is obvious that amphetaminae sulphas produced a lowering of the electrical convulsion threshold, as measured by the product of the volts and duration of the stimulus: it was reduced from 75 to 45 with 5 mg. and to 24 with 10 mg. A corresponding reduction occurred in the milliamperes of current passed.

In Case II the threshold fell from 39 to 26 with 5 mg.; but 10 mg., two treatments later, failed to achieve any effect; three treatments later the threshold fell to 30 on two occasions, but rose again to 45 when the drug was discontinued. A possible explanation of the absence of effect of the drug in treatments 20, 21, and 22 may be that a phase of tolerance was developing which masked the effect, for 5 mg. had previously been effective.

Cases III and VI are good examples and require no explanation. The immediate rise in the threshold when the drug is discontinued is seen in Case VI.

In Case IV some explanation is required, for the threshold increased when 5 mg. of the drug was given. The reason for this is that a too optimistic lowering of both the volts and the length of the stimulus was made, so that it was reduced from 150 volts and 0.3 sec. to 120 volts and 0.1 sec., and five further shocks had to be given before arriving at the effective shock of 150 volts and 0.4 sec. This meant that the factor known as "extinction phenomenon" came into play. After the brain has been stimulated, a phase of negativity develops so that stimulus of greater strength must be given to be effective. This phase lasts 1/2 to 1 hour, so that if the stimuli are given in quick succession the effective amount of current is much greater than if an interval had been allowed between the shocks. On the next occasion, however, when the strength of the current was not altered and only the duration was changed from 0.3 to 0.2, it was effective. The threshold rose again when the drug was omitted.

Case V at first showed a lowering of the threshold, but two treatments later this rose again, and it is likely that tolerance was developing.

In every case, therefore, a reduction of the electrical convulsion threshold occurred, and even in Case II, when it did not occur until the drug had been given on four consecutive occasions, it was eventually reduced below the level obtaining before the drug was given.

Mode of Action of Amphetaminae Sulphas

The manner in which amphetaminae sulphas stimulates the brain is not clear, but since it resembles ephedrine very closely it might be assumed that it acts similarly. Gaddum (1938) has suggested that ephedrine acts in conjunction with adrenaline by a process known as "substrate competition," by which the amine oxidase which is thought to be present in the so-called adrenergic nerves destroys adrenaline, just as choline esterase destroys acetylcholine in the so-called cholinergic nerves. On this supposition it may be assumed that amphetaminae sulphas performs a similar function and that its action is central rather than peripheral.

The effect of other substances on cortical activity has been investigated, and Miller, Stavraky, and Woonton (1940) believe that acetylcholine and physostigmine salicylate, which have a stimulating action on the cortex, exert their effect by a similar process of "substrate phenomenon," the physostigmine preventing the destruction of acetylcholine, since a stronger stimulation results when they are given together than when given separately. Atropine inhibits their action, as it does that of all choline esters. McKail, Obrador, and Wilson (1941) and Williams and Ritchie Russell (1941) confirmed the cortex-stimulating action of these substances and considered that they acted centrally rather than peripherally, for respiratory, blood, sugar, and acid-base changes showed no real effect.

The question of the influence of the change in blood pressure on cortical activity has been studied by Beecher, McDonough, and Forbes (1938), who found that a fall of blood pressure was accompanied by a diminution of electrical activity, whereas McKail, Obrador, and Wilson found that sodium nitrite and amyl nitrite stimulated the cortex. These conflicting findings suggest that the blood pressure has little or no action on cortical activity. The blood pressure was examined in the cases reported here, and readings were made before and one hour after the administration of the amphetaminae sulphas. They are as follows:

	Before	After
Case II	150/80	130/70
„ IV	140/90	160/100
„ V	210/120	240/120
„ VI	160/98	166/110

How far these changes were operative it is not possible to say, but in view of the findings already reported it is possible that they were not so important as the central effect. This is the view of Miller (1937) in the case of physostigmine salicylate, the effect of which was local, facilitating transmission through the cortical synapse, the threshold being reduced.

Summary and Conclusions

On the basis that the initial electrical convulsion threshold varies in different individuals, that a condition of tolerance during treatment occurs resulting in a rise of the threshold, that amphetaminae sulphas is one of a group of drugs which have the property of stimulating the cortex, and that it seems desirable to retain a reasonably low threshold and thus limit the strength of the electrical stimulus, the question of the cause of the heightened threshold in certain types of cases was raised. Assuming that the diminished motor activity associated with depression is due to increased cerebral inhibition, in contrast with that which occurs in schizophrenic disorders, a heightened electrical convulsion threshold might reasonably be expected to result from this inhibition. Now, it is shown by this investigation that cases of depression generally have a higher threshold than cases of other disorders. Investigation also showed that the threshold increased with age, and as depression itself is more commonly found in older age groups there are two possibilities: (*a*) that certain forms of depression raised the threshold *per se,* or (*b*) that age alone has this result. It is impossible to say definitely which factor operates the more strongly, or, indeed, whether the age factor is not really the determinant of the psychosis.

Amphetaminae sulphas, being a known cortical stimulant, was utilized in an attempt to lower the electrical convulsion threshold; in this it was found to be effective, and smaller strengths of electricity could be used.

As regards the mode of action, considerations were discussed showing the likelihood that it exerts its effect centrally rather than by any accompanying peripheral changes, such as the heightened blood pressure. The possibility of the achievement of the central action by a process of "substrate competition," as suggested by Gaddum in the case of ephedrine, was advanced.

In two cases there was some post-convulsion excitement. This was never very great, and may not have been due to the drug, since such excitement has been present after the convulsion when the drug was not employed. No other undesirable effects were observed from the use of the drug: even in the patient with a blood pressure of 210/120 no harm appeared to result with the doses given.

I am indebted to Dr. Thomas Beaton, medical superintendent, St. James Hospital, Portsmouth, for his kind permission to publish this investigation and for his help and interest in it.

ACUTE DISSEMINATED LUPUS ERYTHEMATOSUS: RECOVERY WITH SULPHANILAMIDE

BY

J. E. G. PEARSON, D.M., M.R.C.P.
Hon. Physician to the Connaught Hospital; Assistant Physician in the E.M.S.

The following case is reported because few records have been found of successful treatment of acute lupus erythematosus with sulphanilamide.

Case History

The patient, a married woman, first attended the Middlesex Hospital Dermatological Department in 1933, at the age of 31. She showed lesions of chronic lupus erythematosus on the cheeks, hands, and sternal region which had developed after sunbathing 4½ years previously. During this period she had suffered from toxic hepatitis and anaemia following arsenical treatment for her skin complaint. There was no family or personal history of tuberculosis. Constant supervision and treatment at the Middlesex Hospital included several courses of quinine iodobismuthate intramuscularly, quinine and stovarsol tablets by mouth, and injections of gold thiosulphate, which had to be discontinued owing to a febrile reaction with a rash after the fourth injection. With this treatment her skin condition was kept well under control.

On July 25, 1940, the patient was admitted as an emergency to an E.M.S. hospital. A few days previously she had been taken suddenly ill with acute dissemination of her rash. On admission her temperature was 100.4°, pulse 90, and respirations 20. There was a diffuse patchy erythema, affecting chiefly the cheeks, nose, upper lip, neck, and limbs, some of the lesions showing scaling; the finger-joints were swollen, stiff, and painful; and there was generalized lymphadenopathy, most marked in the cervical glands. In the first 8 days 27 g. of sulphapyridine were administered, and though she felt better, her temperature, which remained swinging, had risen to 103°, and she had more extensive joint pains. Many original skin lesions had faded, but numerous others had appeared, some being discoid in nature.

On the ninth day a macular rash, becoming confluent in places, started on the neck, thighs, and trunk, and rapidly became diffuse: although it was thought to be an erythematous phase of her lupus, the possibility of drug rash was considered, and as the sulphapyridine had evidently had no beneficial effect it was discontinued. A blood culture taken on the fifth day proved sterile apart from a contaminating *Staph. albus,* and a blood count showed red cells 4.5 millions, Hb 86%, leucocytes 7,500 (neutrophils 63%, lymphocytes 37%).

Her condition rapidly deteriorated, and on the twelfth day she was very drowsy, her cerebration was slow, and the temperature reached its peak of 105.4° and remained between 104 and 105° for 36 hours. Pulse 110-124; respirations 24-28. She became completely irrational and delirious, and the tip of the spleen was easily palpated. The position was desperate, and it was decided to attack a possible streptococcal infection anew.

A drip blood transfusion of 1 pint initiated intravenous therapy, and during the next 8 days she received intravenously 21 pints of glucose-saline, 35.5 g. of soluseptasine, and 50 c.cm. of pentnucleotide, with daily intramuscular injections of 6,000 units of antistreptococcal serum. She became rational again, but was very weak, and a stomach tube for feeding purposes was necessary for a further 10 days. During the four weeks after the start of her intravenous treatment she received the following: 35 g. of soluseptasine (first week) and 93 g. of sulphanilamide (last three weeks); 225 c.cm. of pentnucleotide intravenously or intramuscularly; and 144,000 units of antistreptococcal serum intramuscularly. Apart from a few chronic lesions her rash faded completely; her arthropathy disappeared; her haemoglobin fell from 92% to 57%; daily white cell counts showed an almost constant leucopenia, the lowest being 2,500; and almost all her hair fell out. When a rise of temperature to 101°, with a macular drug rash on the trunk, occurred at the end of this period, a blood transfusion of two pints appeared to do good, and a steady recovery followed, although a mild attack of rubella caused a slight scare. The only possible septic focus discovered during her stay was pyorrhoea affecting five teeth in the lower jaw. Extraction was purposely postponed until July, 1941, when it was performed uneventfully.

In Dec., 1941, a tuberculin patch test proved negative, but within five days she had a recurrence of her arthropathy and lymphadenopathy. These subsided under sulphanilamide treatment without any spread of her skin lesions, but further tuberculin tests were considered unjustifiable. Apart from this setback she has remained in apparently good health since her acute attack.

Discussion

Barber (1941) considered that chronic lupus erythematosus can be produced by reaction either to the tubercle bacillus or to a streptococcus; Kelvin (1941) implied that tuberculous toxin can be held responsible for all cases. It is difficult to believe that the latter theory accounts for many of the acute forms of the disease. Sequeira (1927) certainly said that evidence of tuberculosis, including acute miliary and glandular types, could be found in about two-thirds of the patients, but also stated that "the possibility of a non-tuberculous origin of some cases must not be overlooked." Roxburgh (1933) went further in attributing five deaths to streptococcal septicaemia. This termination with or without acute endocarditis has come to be recognized, and although it cannot be taken to prove that the streptococcus is the cause of the whole clinical picture, it is at least suggestive, and is presumably the reason why the sulphonamides were first given a therapeutic trial in this condition. Success has been reported in a small proportion of the patients so treated in America by Weiner (1940), Wile and Holman (1940), and Hopkins (1941), sulphanilamide being the compound chiefly used. In four of the fatal cases on which necropsies were performed tuberculosis was conspicuous by its absence, while a variety of acute lesions were encountered, including pericarditis, pleurisy, splenitis, and glomerulo-tubular nephritis.

Although the aetiology of the condition is not clear, further trial of sulphanilamide therapy is urged for the acute forms of lupus erythematosus without clinical evidence of tuberculosis. In view of the leucopenia accompanying the condition, the simultaneous administration of pentnucleotide seems to be indicated.

I wish to thank Dr. Henry MacCormac for his encouragement, and for permission to publish this case, for which I am also grateful to Surg. Rear-Admiral Whiteside, medical superintendent.

Medical Memoranda

An Improved Pappenheim Stain for Detection of Gonococci in Smears of Pus

In 1938 Sandiford described a malachite green–pyronine counterstain for use in Gram's method. He stated that with it pus cells were bluish green, gonococci bright red, and Gram-positive cocci purple-black. It was in fact a modification of the original Pappenheim and Saathof stain (Pappenheim, 1899), which consisted of methyl green, pyronine, ethyl alcohol, phenol, and glycerol. Walton (1936) used the Pappenheim formula recommended by Conn (1929) and got good results in the examination of smears for gonococci; but Sandiford (1937) could not reproduce them, possibly because he used the original Pappenheim formula. Sandiford found that bacteria and cells and their nuclei were not well differentiated on account of a violet coloration, and in 1938 suggested that this coloration was a metachromatic effect due to the presence of methyl violet as an impurity in methyl green. He therefore substituted malachite green.

According to Conn, methyl green is largely used in stain technology for its metachromatic effect, and is actually crystal violet into which a seventh methyl group has been introduced. This seventh methyl group is very loosely attached and thus there is always some methyl violet present, either because it is not all converted into the higher homologue (methyl green) or because it has broken down. In order to obtain pure methyl green Conn suggested that the commercial dye should be shaken up with chloroform, in which substance methyl violet is soluble.

Walton (1938-9) increased the stability of Pappenheim's stain by incorporating in it methyl alcohol instead of ethyl alcohol. He held that methyl alcohol by virtue of its extra CH_2 groups prevented the seventh methyl group of methyl green from dissociating itself.

THE NEW METHOD

In preliminary work at the Liverpool laboratories it was found that Pappenheim's stain deteriorated within a week even after the substitution of methyl alcohol, and gonococci stained more of a violet colour than a red. It was decided, therefore, to shake up methyl green with chloroform before incorporating it in the Pappenheim stain; this resulted in stabilization of the stain. In the method now used a 1% aqueous solution of methyl green is shaken in a separating funnel for a few minutes with about one-third of its volume of chloroform. The chloroform becomes deep violet and is discarded after separation. A modified Pappenheim solution is then prepared which has the following composition:

Methyl green (Gurr), chloroform-treated, 1% ..	100 c cm.
Methyl alcohol, absolute	10 c cm.
Pyronine G (Gurr)	0.6 g.
Phenol	1.0 g.
Glycerol	20 c.cm.

The solution is allowed to mature for 24 hours and is then filtered into a dropping-bottle before use. The optimum staining period is 1/2 to 1 minute.

If used as a counterstain in Gram's method for smears of pus, Gram-positive organisms stain normally and gonococci brilliant red Most other Gram-negative organisms are a less intense red. Nuclei of the leucocytes are bright blue, but the cytoplasm of the polymorphonuclears behaves differently from that of the mononuclears. The cytoplasm of the latter is red, whereas that of the former is unstained. Endothelial cells have blue nuclei and a cytoplasm of a variable pink.

Sandiford found that the phenol in Pappenheim's solution, normally 2 g. in 130 c.cm., tended to decolorize Gram-positive bacteria after more than 2 minutes, and therefore omitted it from his modification. This fact was confirmed by me, and 1 g. of phenol was substituted. With this amount the decolorizing action was minimized, although it was of little importance because the staining period was much shorter than that used by Sandiford. The staining intensity of Pappenheim's solution is lessened if phenol is omitted.

In a comparison of Sandiford's modification of Pappenheim's stain with that described by me it was found that gonococci were more distinctly red by the latter and easier to detect against the clear unstained background of the polymorphonuclear cells. Moreover, the contrast of the brilliant-red gonococci and the bright-blue nuclei by my modification was greater than that by Sandiford's, with which gonococci were red and the pus cells green with bluish-green nuclei

The modified Pappenheim stain here described was primarily intended for use in the examination of smears for gonococci, either directly or as a counterstain, but it is very suitable for blood films, particularly in the differentiation of the mononuclear leucocytes. The stain is also excellent for cerebrospinal fluid containing meningococci, and any amount of pyronine from 0.5 to 1 g. will yield good results.

The keeping quality of the modified stain has not yet been determined, but it is longer than 3 months and the solution is effective after Sandiford's has begun to deteriorate.

The Vitamin C Saturation Test

This test, as modified by Harris and Abbasy (*Lancet*, 1937, 2, 1429), affords useful and reliable information concerning the vitamin C reserves of men. During my year as lieutenant in the R.A.M.C. I carried it out on 1,200 soldiers according to a scheme drawn up by the Directorate. I performed several thousand titrations, and in the first tour each involved the usual simple calculations, taking into account the period of retention, the volume of the sample of urine, the burette reading, and the variable strength of the reagent—2:6-dichlorophenol-indophenol. These were tedious. The following is the procedure followed in the second tour; it is described here because it saved so much time both in the titrations and calculations.

As before, the men were dosed with 0.75 g. of ascorbic acid in water at 7.30 a.m. They emptied their bladders at 10.30 a.m., and a two-hour period of retention was adhered to rigorously. This is better than three hours, which in winter is too long. The samples were collected at 12.30 p.m. in numbered 2-lb. jam-jars, and instead of measuring the volume, which for 100 samples took about 1½ hours, each sample was made up to 500 or 1,000 ml. with tap-water. While an assistant did this, 10 ml. was pipetted off from each and run into a 6-oz. medicine bottle, numbered on shoulder and on cork. These bottles had previously received 1 ml. of glacial acetic acid.

This method obviates the addition of large quantities (30 to 50 ml.) of reagent in titrating the more concentrated urines. By taking 2.20 ml. of acidified sample for titration (namely, 2 ml. of urine), using a pipette graduated to the tip, with reagent adjusted so that 1 ml. was equivalent to 0.1 mg. of the pure vitamin, convenient readings were obtained. These were around 0.2 ml. for the initial low values of the first day, rising finally to about 6 to 8 ml. Saturation was taken to be when 50 mg. was excreted in a 3-hour period, or correspondingly for two hours. It is convenient to use the numbered corks to identify the 2-ml. portions removed to test-tubes for titration.

The reagent was adjusted to correspond to 0.1 mg. of vitamin, using 100-mg. portions weighed before the tour (*not* a bought tablet or a 1-g. tube as sold—these are not prepared as standards, and do not justify the implicit faith in their exactness that one sometimes finds). Tap-water had to be used, but this introduced no appreciable error. The standard must be titrated immediately after preparation.

The method appears to be entirely reliable, and will differentiate groups of men living under slightly different conditions. This may best be appreciated by plotting the number of daily doses required to saturate on the vertical axis and the number of men saturated by that day on the horizontal axis; namely, the sum of those saturated on first, second, and third days—say 60%—would be plotted at 60 for third day. Another way of assessing is to plot for each group the number unsaturated on some selected day; this shows up deficiencies. Thus, for example (an entirely hypothetical case), suppose one group of men had 5% remaining unsaturated after six doses and another had 50%, the difference could be strikingly shown in a graph. If, however, the two groups were close together they might best be differentiated by choosing a smaller number of doses for a comparison. Thus two groups which gave the same percentage of unsaturated after, say, five doses might be separated by one of them having a larger number unsaturated after four doses.

Plymouth.

Reviews

TUBERCULOSIS STUDIES FROM U.S.

Modern Aspects of the Anti-tuberculosis Program. By J. Burns Amberson, Kendall Emerson, Wm. Charles White, and Louis I. Dublin. University of Pennsylvania Bicentennial Conference (Pp. 38. 3s. 6d.) Philadelphia: University of Pennsylvania Press.; London: Oxford University Press. 1941.

The four papers in this booklet were read at the University of Pennsylvania Bicentennial Conference and all will repay close study. Dr. J. Burns Amberson's subject is the "Evaluation of the Early Lesion in the Clinical Approach to the Control of Tuberculosis," and his remarks on the management of the early lesion discovered by routine radiological examination are significant. "The only choice, therefore, if the physician and patient wish to accomplish maximum results at the most opportune time, is to treat these newly developed lesions promptly and carefully [bed rest for several months being essential]. Promptness is of the greatest importance. The rapidity of some of the early changes indicates that the ultimate fate of many patients is determined within a few days or weeks after the first diagnosis." Dr. Amberson bases this conclusion on clinical investigation during the past ten years among nurses, medical students, house officers, and other hospital personnel, details of which are shortly to be published. It supports the view of those who maintain that any worthwhile results from mass radiography will be obtained only if the examinations are repeated at relatively short intervals and enough beds are available for the effective rest treatment of those discovered to have active lesions. To quote Dr. Amberson again, ". . . a freshly developed pulmonary lesion is not merely a mechanical problem to be solved by a mechanical means. The very development of the lesion is an indication of inadequate resistance which only time and rest treatment can restore most effectively and surely. To ignore this is to neglect the greatest bulwark against relapse in later years, and it is the physician's duty to take the long view."

Dr. Emerson's discussion of "Tuberculosis Control from the Point of View of a Voluntary Public Health Agency" will be of less interest to readers in Great Britain, where much of this work is the function of local authorities. "The Place of Medical Research in the Anti-tuberculosis Campaign" is described by Dr. White, chairman of the Committee on Medical Research of the National Tuberculosis Association. Planned systematic research in tuberculosis is not very conspicuous in this country, and the National Tuberculosis Association in U.S.A. may well be proud of its record. Finally, Dr. Dublin, of the Metropolitan Life Insurance Company, discusses "The Outlook for the Eradication of Tuberculosis," mainly in the U.S. It is perhaps carrying simplification too far to consider that the tuberculosis problem "largely simmers down to the discovery of cases and to providing adequate care and treatment for the cases when discovered." On the other hand, we agree that "there has been altogether too much hesitation and complacency with respect to tuberculosis as a disease to be conquered. There is good evidence that tuberculosis will not be much more difficult to eradicate than have been other communicable diseases. But we must attack it with the same energy, skill, and forethought that we have employed against diphtheria or typhoid fever."

It was a good idea to publish the four papers in this form, for in these 38 pages there is indeed *multum in parvo*.

SURGICAL TREATMENT

Textbook of Surgical Treatment, Including Operative Surgery. Edited by C. F. W. Illingworth, M.D., Ch.M., F.R.C.S.Ed. (Pp. 528; illustrated. 28s., plus 8d. postage) Edinburgh: E. and S. Livingstone. 1943.

This textbook of surgical treatment is compiled by eighteen Scottish surgeons under the editorship of Prof. C. F. W. Illingworth of Glasgow. It is of comfortable size, is well printed in clear type, and covers the field of general surgery well; specialties such as rhino-laryngology and gynaecology are not included.

Surgical treatment implies rather more than operative surgery, and while giving due prominence to the operation, which is usually the central and great event in surgical management, this book deals also with the pre-operative and post-operative care of patients, and also with the conservative treatment of surgical conditions for which operation is not required. In this sense, therefore, it is rather a practical guide to surgical case management than a textbook of operative surgery, and in order to keep the size within reasonable limits descriptions of operations have for the most part been confined to details of single procedures rather than to a variety of methods which are so often put before one in books on operative surgery. For this reason, however, there will not be general agreement with all the procedures advocated. Inconsistencies are bound to occur in such a work as this, and while Knight's name is mentioned in connexion with sympathectomy for cardiospasm, Oldham and Rogers, whom we associate with renal sympathectomy and sympathectomy for supra-oesophageal spasm respectively, are given no mention. We should have liked to see more illustrations: such as there are, especially the line drawings, are good, but there could with advantage be more of them in certain sections; some, such as "Affections of the Bladder and Urethra," are well illustrated, while others are lacking in this respect.

This is a well written, sound, and essentially modern textbook which we predict will prove popular and run into future editions. It will be valued, we believe, not only by medical students in the Scottish schools, to whom it will of course have special appeal, but by students throughout the English-speaking world.

STOIC PHILOSOPHY IN VERSE FORM

Marcus Aurelius: A Rendering in Verse. By John Lyth. Preface by Prof. Gilbert Murray. P.E.N. Books. (Pp. 29. 2s.). London. George Allen and Unwin, Ltd. 1942.

Those, in Prof. Gilbert Murray's words, "who have felt the magical beauty of Fitzgerald's *Omar Khayyám* must sometimes have wondered whether some more adequate and less helpless philosophy would not yield a similar harvest of poetry."

Dr. Lyth has presented in rhythmical form the essence of the Stoic philosophy as Marcus Aurelius interpreted it in actions and words. No doubt the genial influence of Horace, to say nothing of our own Landor and Peacock, makes men of literary tastes think more kindly of Epicureanism than Stoicism. But we must remember that Horace's noblest characters were Stoics, and Stoicism, practical Stoicism, the creed of most of the world's noblest characters. Dr. Lyth's charming verses often remind us of this:

> Live out thy life as at thy journey's end;
> But if mayhap men prove too strong for thee
> Then get thee gone, nor dream thy death to be
> The greatest trial which the gods can send.
> I quit this room, whose smoke gives me offence—
> Is this a matter of great consequence?

One remembers: "But you also, judges, must regard death hopefully and must bear in mind this one truth, that no evil can come to a good man either in life or after death, and God does not neglect him. So, too, this which has come to me has not come by chance, but I see plainly that it was better for me to die now and be freed from troubles."

In these times Dr. Lyth's poetry will bring comfort and a quiet mind to many readers, and even a sense of pride that so many, neither philosophers nor emperors, have been faithful to their ethical creed, even unto death.

Notes on Books

We welcome the fifth edition of one of the well-known Edinburgh "Catechism Series"—Part V, *Anatomy*, which comprises the thorax and lymphatic system (E. and S. Livingstone; 1s. 6d.). This has been enlarged and revised by Mr. C. R. WHITTAKER, and it has the characteristic feature of brevity combined with clarity which distinguishes the series in general. The part now under consideration will be of value to students who wish to revise the essential points in the anatomy of the thorax and lymphatic system and owing to the mode of presentation—Question and Answer—it will assist them to focus their attention on those facts which should be known for examination purposes. It will also serve to impress firmly on the mind knowledge which has already been obtained through dissection and classwork, and, so to speak, register it in the brain in such a way that it will be available when, later on, it is required in ordinary practice. The book is not illustrated and makes no claim to originality or to the recording of any of the latest advances in scientific work. The inclusion of such matter is, however, outside the intention of what is primarily designed for the use of the average student and to help him to concentrate his attention on well-established and fundamental facts, a knowledge of which is essential for the practice of the medical profession.

Preparations and Appliances

IRON LUNG IMPROVISED IN A WARSHIP

Surg. Lieut.-Cmdr. A. C. K. YATES, M.B., Ch.M., F.R.C.S.Ed., R.N.V.R., writes:

The following is an account of the improvisation of a Drinker apparatus on board H.M.S. *Hermione* and the result of collaboration with the S.M.O. of H.M.S. *Ark Royal* after manufacturing a similar unit.

On Oct. 26, 1941, an able seaman was transferred from H.M.S. *Hermione* to the local military hospital suffering from follicular tonsillitis and was placed in close contact with another patient who was found later to have developed acute anterior poliomyelitis. The latter patient was transferred to the Colonial Hospital, where it was found necessary to place him in a Nuffield iron lung (the only one in the locality). A few days later the A.B. also developed symptoms and signs of acute anterior poliomyelitis. He rapidly showed signs of paralysis and began to experience respiratory embarrassment. At this stage H.M.S. *Hermione* was visited by the medical liaison officer of the port, who requested on behalf of the hospital authorities that 12 to 15 hands from the ship should be held in readiness for immediate call to carry out artificial respiration. Also, it was suggested that H.M.S. *Hermione* should attempt the manufacture of an iron lung, as the only available one was in use and it was doubtful if a further supply would reach the port in time. The warrant shipwright was consulted, and he, with two shipwrights and a blacksmith, was accompanied to the Colonial Hospital to inspect the Nuffield iron lung in use. It was the first occasion any of the shipwright's party had ever seen the apparatus, and after making a few sketches and notes they returned to the ship and immediately set to work, using only materials available in the workshop, with the exception of a sorbo-rubber neckpiece (which we could have improvised) obtained from the hospital. In 14 hours they produced a replica of the original, their work being completed at 2 a.m. An experimental subject was then placed in the apparatus, which was found to answer perfectly.

FIG. 1

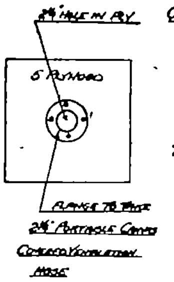

FIG. 2

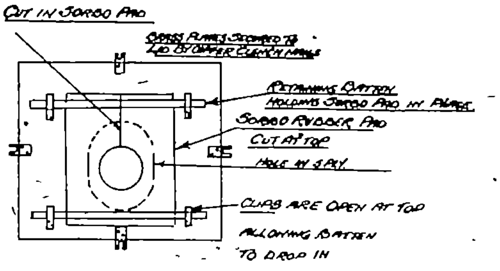

FIG. 3

The improvised "lung" was then transferred to the military hospital at 3 a.m., as an urgent request for it was received just on completion. Parties of four men in each were detailed from the ship's company to work the hand bellows, each man pumping in 15-minute shifts and each party being relieved every four hours. The work was carried out daily to the complete satisfaction of the hospital authorities and to the great benefit of the patient.

Forty-eight hours later H.M.S. *Ark Royal* transferred a case of anterior poliomyelitis to hospital and, hearing of H.M.S. *Hermione's* experience, consulted us. Although their patient showed no signs of respiratory involvement it was considered advisable to be prepared. After obtaining advice from the *Hermione* and seeing their apparatus in operation, and after a preliminary inspection of the iron lung at the Colonial Hospital, *Ark Royal* with their more extensive workshops were enabled to produce a unit in under seven hours.

After consultation between *Hermione* and *Ark Royal* we have come to the following conclusions: first, that from the experience of these two cases it is obvious that a unit, sufficient for the immediate purpose and at little expense, can be put together in a very short time; secondly, that the unit can be made from materials readily available in H.M. ships, shore establishments, and probably also in civil institutions which have their own workshops. The following are particulars of the apparatus:

The body is made of five-ply boards secured to 1½ in. by 1¼ in. fillet pieces. The hose joining bellows to body should be of a non-collapsible variety—a length of portable ventilation hose which is wire-stiffened inside is very suitable. The hose should be approximately 6 ft. in length to allow pumping to be done in an adjacent room. The bellows should be 2 ft. in diameter, with a rise and fall of at least 9 in. The bottom of the bellows is pulled by handle towards the top, the top of the bellows being secured to a suitable platform 14 in. high, for the man to stand on when pumping. If time permits, four vertical guide rods should be fitted to ensure that the bottom of the bellows rises and falls vertically, thus making pumping easier. A stretcher-board of five-ply should be fitted inside the bottom of the body of the unit, running the whole length, and have two rope beckets at the entrance to enable it to be withdrawn easily when the patient is in the unit. A shaped mattress to fit this board should be made. The action of the relief valve is similar to that on a Service respirator.

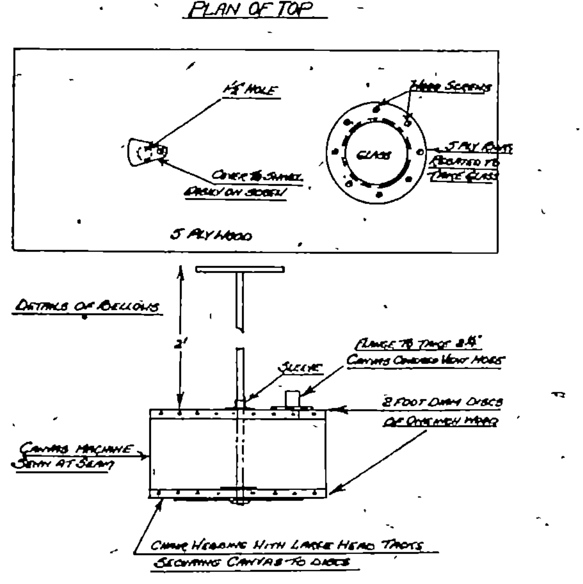

FIG. 4

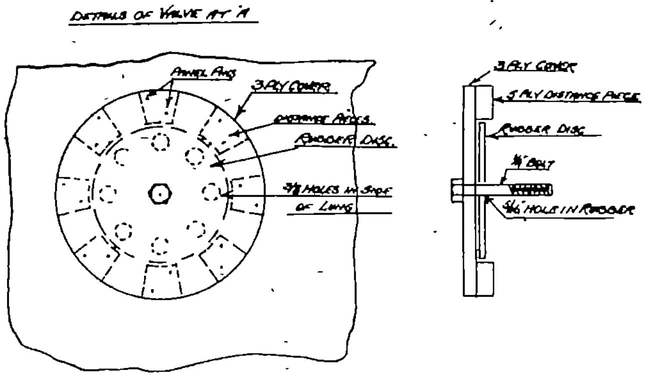

FIG. 5

Pumping is done by relays of men, four to a watch of four hours, each man having 15 minutes' duty every hour and 45 minutes off duty. These men did this easily and without fatigue.

This work, although primarily of medical importance and under medical supervision, was done entirely by the shipwrights of both ships with a little assistance from each ship's engineering department, and it is due to them that these jobs were completed so efficiently and in so short a time. We are indebted to them also for the technical details and drawings. I am also indebted to Surg. Cmdr. McCoull of H.M.S. *Ark Royal* for his co-operation in this report.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY FEBRUARY 27 1943

THE KING'S FUND

Although the title was proposed by its first royal President, King Edward's Hospital Fund for London (or the Prince of Wales's Fund, as it was called at first) is not very happily named. "King's Fund" suggests nothing more than a gilt-edged banking account, and the Fund is much more than a collecting and distributing agency. It has been for forty-five years an integral part of the hospital service of London, the buttress of voluntaryism in the South of England, has shaped hospital policy, and has prompted or assisted many developments which are now commonplaces in the institutional care of the sick. Above all, it has vastly broadened the basis of public support for hospitals. When it began its work not one person in a hundred contributed to these institutions. A Fund under royal auspices—its President must always be the son, brother, or grandson of the sovereign—was able to call forth magnificent donations from imperial financiers and Indian princes, but it also called forth the modest guineas of the middle class and even the shillings and sixpences of the poor, for it was largely at the instance of the Fund that the Hospital Saving Association for London was founded in 1923.

To commemorate the service of the Fund in five reigns a short and very readable history has been prepared.[1] Apparently it was Edward VII himself, then Prince of Wales, who conceived the idea of the Fund as a memorial of his mother's sixty years' reign, though there are other figures in the background, notably Sir Alfred Fripp and Sir Henry Burdett, who may have whispered a word in the royal ear. The preliminary discussion at Marlborough House in 1897 was attended by dukes, bishops, bankers, and Members of Parliament, also by Lord Lister and the Presidents of the Royal Colleges. Lord Lister was the only medical man on the general committee of ten members appointed to work out details. The first object of the Fund was to secure from £100,000 to £150,000 in annual subscriptions from people who were not already contributing to hospitals. The plan was not altogether welcomed by the hospitals themselves. The prospect of additional revenue was pleasing enough, but they feared that ancient liberties would suffer, that concentration of services, perhaps amalgamations, would be forced upon them. The future Edward VII was a philanthropist; but he was a great stickler for efficiency, and the hospitals of those days, in their administration, were, frankly, inefficient. They were jealous for their isolation, they were competitors for the purse of the charitable, and the idea of working together or profiting from common experience was remote. At that time, although there were rate-aided workhouse infirmaries, the municipal hospital had not arisen to challenge and stimulate voluntary effort. The first grants made by the Fund may well have exacerbated the feeling. Guy's, which at that time was falling down, received £6,000, and the London £5,000, but Charing Cross, Middlesex, King's College, and St. Mary's received only £1,000 each, and St. Bartholomew's, happy in its endowments, nothing at all. The benefactions were at first made to hospitals within a seven-mile radius from Charing Cross; it was on the proposal of Lord Lister that the radius was extended to nine miles; and now the area is conterminous with the metropolitan police district, with a population of 8,500,000 and 168 voluntary hospitals.

At the time when the Fund began its work 687 hospital beds in London had been closed for lack of means. Within a year 185 of them were reopened, and a few years later there were no closed beds at all. Another critical period came after the end of the last war, when, in the aggregate, the expenditure of London hospitals was exceeding their income by 10%, and there was a prospect of the wholesale closing of wards. It was at this time that the first Minister of Health, Dr. (now Lord) Addison (never "Sir Christopher Addison," as this brochure calls him), appointed the Cave Committee, on the recommendation of which the King's Fund functioned as the Voluntary Hospitals Committee for London. Largely because of the Fund, both for its direct grants and the enthusiasm it inspired, the aggregate deficit was wiped out by 1924, and there was a surplus of £227,000. Well might the Prince of Wales (afterwards Edward VIII), speaking at a special meeting of the council in that year, ask whether anyone could now suppose the voluntary system to be dead or dying. The annual distributions of the Fund rose from £50,000 at the end of the reign of Queen Victoria to £150,000 at the end of the reign of Edward VII, and when George V died they had been £300,000 for each of the last three years.

But, as we have tried to make clear, the Fund has been far more than a mere treasure chest. Among the achievements which are to be placed to its credit are the encouragement of pay beds (it promoted the Voluntary Hospitals (Paying Patients) Act, 1936), a better organization of the out-patient system, the improvement of deficient radium supplies at London hospitals, the establishment and maintenance of a nursing recruitment centre, a pension scheme for nurses and hospital officers, a uniform system of hospital accounting, an amelioration in hospital routine whereby patients were wakened at a later hour, more rapid admission of urgent cases, leading to the foundation of the Emergency Bed Service, now dovetailing into the Emergency Hospital Scheme, and a reduction in the number of hospital flag days from seventy-seven in the year to two, without loss of revenue. The Fund took a leading part in the discussions which followed the Local Government Act, 1929, with a view to working out principles of co-ordination between voluntary hospitals and the new municipal and county service. It was a pioneer in this field, for although its concern is for voluntary hospitals, yet the chairman of the London County Council, the head of the greatest municipal hospital authority in the world, has always been a member of its general council. In the new era of co-operation between these services which has been forecast by the present Minister of Health the Fund will no doubt find new tasks to fulfil. Some might have supposed that such a Fund had no history, only a succession of balance-sheets, but that is far from being the case, and this little book forms a useful footnote to the annals of social progress in our time.

UNPADDED OR SKIN-TIGHT PLASTER SPLINTS

In a recent legal action against a medical man for alleged negligence in the treatment of a forearm fracture, confusion was caused by the use of the term "skin-tight" as applied to a plaster splint, and by statements quoted from authorities purporting to show that encircling plaster bandages were to be condemned. The term "skin-tight plaster" is used not for a tight plaster but for one which is applied direct to the skin. Unpadded, or so-called skin-tight, plasters were reintroduced by Böhler of Vienna as an economy measure during the last war, when there was a scarcity of cellulose and other padding materials in Austria. He found that when such bandages were evenly applied the risk of constriction was no greater than with padded plasters, and that the risk of pressure sores occurring beneath them was, in fact, less, because of the more perfect moulding which was possible round the contours of the limb. For the same reason the immobilization of fractures was found to be more perfect by the unpadded plaster method. Tension within a fractured limb normally rises an hour or two after the injury, the rise being due to vascular damage and haematoma formation. For this reason some surgeons have advocated delay in reduction until swelling is maximal. The disadvantages of this are, first, that it is more difficult in some cases to get satisfactory reduction, and, secondly, that the fragments are apt to slip apart when the swelling has subsided inside the plaster splint. These difficulties are avoided if the fracture is reduced before swelling has occurred and a plaster splint is applied immediately, but the drawback here is that the plaster does not permit swelling beneath it, and, therefore, relative venous and lymphatic obstruction is apparent in swelling of the peripheral portions (fingers and toes) of the limb left uncovered by the plaster.

---

[1] *King Edward's Hospital Fund for London, 1897-1942.* By Frank D. Long. (The Fund Offices, 10, Old Jewry, E.C.2.)

A third possibility is to use a temporary splint lightly bandaged until the swelling has subsided, and wait several days until reduction can be performed. Even then the manipulative procedure is apt to cause fresh swelling within the plaster cast and the same careful after-treatment is required. Delayed reduction of this sort has its own risks where a severely displaced fracture may produce important vascular or nervous complications. Rise of tension with a well-applied plaster is, therefore, to be considered normal, and is not much less with a padded plaster than with one that is unpadded; it is a great disadvantage of any plaster technique, however perfect. Elevation of the limb reduces the tension by diminishing the flow of arterial blood into it, and helps lymphatic absorption and venous drainage. Should rise of tension become dangerous in spite of elevation, further relief can be obtained by splitting the plaster and subjacent padding (if any). The presence of swelling peripheral to a plaster splint is thus of itself no indication that the splint has been incorrectly applied. Obviously, therefore, the fact that the surgeon has ordered a plaster to be split is not an admission that he has applied the plaster wrongly in the first instance. Nor can anyone who has not seen the case in the acute stage decide whether a particular surgeon was right or not in applying a plaster before natural swelling either had occurred, become maximal, or had subsided. The judgment of "the man on the spot" is paramount, and he himself must be judged upon the consideration he has given to the problem in the light of the skill and attention that can reasonably be expected of him.

As to the methods suitable for the application of unpadded plaster splints, it is necessary to draw attention to statements which to the layman, and particularly the lawyer, appear conflicting. This is important, because two well-known textbooks both give details that are confusing. Böhler, for example, states that "the use of encircling (roller) plaster bandages without padding is to be strictly forbidden on account of the danger of pressure sores." On the same page he then describes a method of applying plasters as follows: "First of all a plaster splint (slab or flat) is applied and over this an encircling bandage. This must not be taken to imply a circular plaster bandage in the old sense. The plaster bandage should not be drawn tight but only lightly applied." Later in the book, when dealing with Colles's fracture, he describes a method by which a plaster slab 6 in. wide is applied to the extensor surface, moulded carefully round the limb, and completed by a calico bandage; but he adds that "care must be taken that the starch bandage is not applied too tightly, because in contrast to the plaster bandage it contracts on drying." Watson-Jones,[1] in his discussion on plaster technique, gives in a series of pictures and their legends a method in which a slab on the extensor aspect of the wrist is completed by a wet open-wove bandage. On the next page he describes the complete plaster-cast technique, in which "one or more slabs are carefully moulded in position with a wet, soft bandage," and finished by the application of an "ordinary plaster bandage in a circular manner." Both writers, therefore, approve the carefully applied encircling plaster bandage over one or two slabs.

There is a possibility that one or other of the statements may be taken to uphold a view which was not intended by the author. Used intelligently and with adequate care, single plaster slabs or double plaster slabs with encircling plaster or encircling gauze bandages are all recognized and approved procedures. Those who are in a position to teach plaster technique must see to it that students (and this includes medical practitioners) appreciate the need for precision in the application of these methods and the importance of adequate supervision and proper after-treatment. Finally, we would urge the adoption of the adjective "unpadded," which is less misleading than "skin-tight."

DOCTORS AGREE ABOUT PASTEURIZATION

The correspondence that followed the moderately worded leader on pasteurization of milk in the *Journal* of Dec. 19 showed once again that pasteurization is one of those subjects that tend to generate more heat than light. It is a great pity that medical men who oppose pasteurization support their case by misstatements of fact, or by ignoring those facts which are available to anyone who will take the trouble to spend an hour or two in a medical library. It is a pity, because their misstatements and ill-informed views are given much prominence in a press often enough, unfortunately, more anxious to please certain interests than to get at the truth of the matter. It has frequently been said that the first line of health defence in this country is the general practitioner, and perhaps too little credit has been given to him for the daily advice and instruction he gives his patients on all matters of health and hygiene. But with so little time at his disposal, the G.P. cannot be expected to sift the scientific evidence in books and medical periodicals on behalf of the pasteurization of milk. While it may seem to him to be self-evident that if you want to prevent 2,000 children dying every year from bovine tuberculosis you should prevent the bovine bacillus from reaching the child population of this country, the stubborn—but apparently humane—opponents of this obvious public health measure seek to trip him up by specious arguments. With a few exceptions the doctors of this country agree—and have agreed for a number of years—that pasteurization is essential. So that medical men may have the facts at their finger-tips, we have asked Prof. Selby Wilson to put the gist of the matter in the form of question and answer. If every doctor in practice were to keep his patients and influential people in the locality in which he works informed of the facts presented in Prof. Wilson's admirable summary, then in time that indefinite thing called "public opinion" might be able to overcome the powerful vested interest which by its opposition has been responsible for the deaths of thousands of children through bovine tuberculosis, not to mention the suffering and crippling caused in those who survive this and other infections conveyed by milk.

The situation was summarized pithily by Sir Alfred Webb-Johnson at a deputation from the British Medical

Association which was received last week by the Minister of Food, when he said that the Government as controllers of the organization and sale of milk had a moral responsibility to take adequate steps to prevent infection from it. Lord Woolton has a great respect for facts and for the opinion of experts; it is because of this that the conduct of his Ministry has received such unstinted praise. The medical profession are glad that he has taken this trouble to be informed about the pasteurization of milk. The statements made by the influential deputation, introduced to the Minister last week by Prof. R. M. F. Picken, are published elsewhere in this *Journal.* We hope that every medical man will read Prof. Wilson's article and the account of the deputation, and, armed with this ammunition, will carry the war energetically into the enemy's camp—that is, the camp of those who oppose pasteurization.

THE CARE OF THE NEWBORN

Two inquiries into the incidence of breast-feeding, one relating to children in welfare centres and the other to children in the casualty and out-patient departments of a city hospital, have lately been made in Birmingham, and the statistical results and conclusions are given in a report issued by the British Paediatric Association. In the "welfare" group between four and five thousand records were obtained through the co-operation of health visitors. The conclusions of the health visitors are that the incidence of breast-feeding has not been materially altered by the present emergency, with its large demands for female labour. In areas where married women have not been accustomed to work in the factories they are still not entering such employment while they have a baby under one year; and where they have been accustomed to work in factories they return to such employment at no earlier date—that is to say, they wait until the baby is at least two months old. Influences which affect breast-feeding are said to be the shopping queues, part-time work, emotional disturbances (such as anxiety concerning a husband on war service), and, above all, the action of the doctor. The doctor is said to be more responsible than any other single factor for weaning babies, taking babies off the breast whenever there is any difficulty. But on the whole it is considered that infants are now better cared for than they were in peacetime, largely because munition workers are now getting higher wages. Of 2,698 "welfare" infants, the proportion who continued to be breast-fed after three months was 39% in the case of first babies and 42.7% in the case of second or later children. The inquiry into the condition of babies seen at hospital with their mothers covered a much smaller group, and a group which obviously had to be divided into the "sick" and the "well." Of the babies in the "sick" category nearly 20%, and of those in the "well" category 34%, were breast-fed after the third month. Several interesting conclusions are reached from the voluminous statistics presented, but the most interesting is that when the results are compared with those of a similar inquiry made in 1938 it does not appear, at least in Birmingham, that weaning is associated with the mothers' employment in industry.

The British Paediatric Association has also issued a report of its subcommittee on neonatal mortality. It is stated that immaturity accounts for about 50% of neonatal deaths, but that this usual death rate can be reduced to below 20% by special paediatric care, supported by skilled nursing in suitably equipped units. The report urges the setting up of a "premature unit" in every maternity hospital and in all large children's hospitals, the unit to be in charge of a paediatrician possessing experience in neonatal work. Of the other causes of neonatal mortality, the second to be mentioned is birth trauma, the prevention of which is a problem for obstetricians, general practitioners, and midwives. The incidence of asphyxia neonatorum could probably be reduced by a higher standard of ante-natal care and by consultations with obstetricians and physiologists on the question of analgesics and sedatives and on that of methods of resuscitation. Another set of problems is concerned in the reduction of incidence of infective and toxic conditions among the newly born. This is held to be largely a question of nursing. Neonates, particularly those who are premature or suffer from congenital weakness, and therefore are particularly prone to infection, should not be herded together. They should be in a special unit designed on the cubicle system. The subcommittee suggests that a committee of paediatricians, obstetricians, and public health experts should be set up to discuss the various aspects of neonatal mortality and morbidity, especially the health of the pregnant woman, the relative advantages of domiciliary and institutional confinements, and the encouragement of breast-feeding. On this last point it urges that breast-milk banks or "pools" should be set up in maternity hospitals or other suitable centres. Another recommendation is that the Central Midwives Board should include at least one paediatrician, and that the final examination for the C.M.B. certificate should include questions, set by a paediatrician, on neonatal care.

PROGESTERONE AND VITAMIN E

Recent efforts to reduce neonatal mortality may cause us to forget that the problem of habitual abortion, although much less urgent, still awaits solution. Vitamins and hormones are apparently both implicated, but the evidence is somewhat contradictory Recent published work[1-2, 3] in German journals suggests that a combination of the corpus luteum hormone (progesterone) and vitamin E is particularly beneficial. Certainly the figures, although small, are suggestive, and indicate the need for further study. Since it is possible that some of the abortions are due to hormonal dysfunction, while others are the result of vitamin E deficiency, combined therapy would naturally be more beneficial if patients from both categories were included. There is some evidence, however, that vitamin E exerts its effect by acting through the ovarian hormones. Thus, a resting thyroid gland can be activated either by follicular hormone or by vitamin E, but the latter is inactive in castrated animals. Stähler and his co-workers,[4, 5] impressed by the potentiating action of vitamin E on progesterone, have attempted to analyse this effect. This they have done by determining the dose of progesterone required in young rats and rabbits to complete the uterine cycle which had been initiated by oestradiol benzoate. There appeared to be little doubt that much more progesterone was necessary when no vitamin E was given. The potentiating effect did not appear until the fifth day of vitamin therapy and was not maximal until the thirteenth. The results of oral administration were more marked than were those of injection of an oily solution. As for the action of vitamin E on other gonadal hormones, it was found to have a slight potentiating effect on oestrogens, but did not increase the production of prolan A or lead to any histological changes in the anterior pituitary. Vitamin E did not significantly alter the growth curve in rabbits, but progesterone caused an increase in weight proportional to the dose. In rats, on the other hand, vitamin E led to a transient loss of weight which was greater than

that accompanying complete starvation. It also favoured the production of corpora lutea in rats, but in rabbits, although the follicles became more fully developed, they did not reach the luteal stage. These facts show the need for caution in applying to one species the experimental results obtained in another. This is further demonstrated by the fact that in rats glycogen appeared in the endometrium as a result of progesterone action, while in rabbits it was often present without this hormone. It is obvious that the action of vitamin E on the endocrine system is a complex one, and much must still be done before the interrelationship is clarified. The effect of combined hormone and vitamin therapy has still to be determined, and individual case reports, while possibly of interest, merely cloud judgment. The next steps must be further experimental work, and, even more important, the accumulation of a sufficient number of carefully controlled clinical observations from ante-natal clinics and maternity hospitals.

INCUBATION PERIOD IN TUBERCULOSIS

The problem of tuberculosis control might be greatly simplified if the onset of the primary infection were associated with a generalized rash. Unfortunately erythema nodosum only occasionally helps, and even this association is not recognized widely enough at present. It is not surprising, therefore, that the incubation period of tuberculosis is seldom discussed, although attempts, recently summarized by Wallgren,[1] have been made to investigate it in the past. He lays down certain criteria for estimating the incubation period—that is, the interval between infection with tubercle bacilli and the first appearance of the primary tuberculous lesion. Wallgren found in the literature only 13 cases which fulfilled these criteria. He has added 23 of his own, and divides the 36 cases into two groups: (1) those in which the end of the incubation period and onset of allergy could be determined only by means of tuberculin tests; and (2) those in which the end of the incubation period was determined by manifestations of primary tuberculosis. In this second group were cases with "initial fever" and erythema nodosum and cases with fever but no erythema nodosum. Each of these subgroups was divided again into patients who later developed clinical signs of primary tuberculosis, and those in whom the diagnosis was established only by a positive, following a negative, tuberculin test in relation to the erythema nodosum and/or "initial fever." The 36 cases were also classified into (*a*) those in which contact could definitely be assumed to have taken place for no longer than a day (13 cases), and (*b*) those in which the contact covered a period of two days to two weeks (23 cases). Only in (*a*) could the incubation period be determined with accuracy, and analysis of the case reports showed that it was under 30 days in one case, 30 to 35 days in three, 35 to 40 days in five, 40 to 45 in two, 46 to 50 days in one, and over 50 days in one. The incubation periods in the other 23 cases, allowing for a minimum period of contact of two days and a maximum of three weeks, are indicated in the following table:

	Incubation Period (Days)									
	< 15	15–20	20–25	25–30	30–35	35–40	40–45	45–50	> 50	Total
Minimum number of cases ..	1	4	1	6	1	7	3			23
Maximum number of cases ..			2	1	4	3	6	6	1	23

From these findings it can be concluded that, although the incubation period is variable and may rarely be under two weeks or more than seven weeks, in most cases it is four to seven weeks. The practical importance of this in connexion with the examination of contacts and tuberculin testing is obvious.

SILICOSIS IN SWEDEN

All those interested in silicosis will find Torsten Bruce's study of the extensive investigations he carried out into the incidence of the disease in various industries in Sweden both timely and helpful.[1] Altogether 2,631 workers in porcelain, iron, silicate, sandstone, quartz, and coal-mining were examined, and also 500 others who were incapacitated, or in receipt of a pension, or following occupations that were presumed to be associated with silicosis. Radiological appearances were classified according to the criteria laid down by the International Silicosis Congress in Johannesburg. Silicosis developed in different occupations at apparently strikingly different rates. Thus severe silicosis developed most rapidly in quartz workers, among whom silicosis Stage 3 might be met after less than fifteen years' work, whereas among porcelain workers such a stage was not reached until after at least twenty-five years. It follows that in certain occupations silicosis might lead to incapacity while the individual was still in the prime of life, while in others this stage might not be reached until the worker was due to retire. Further, in cases in which Stage 1 silicosis took a relatively long time to become manifest the disease did not progress in the following five years; whereas in cases in which Stage 1 developed rapidly the disease might progress even if the work responsible was given up. Although the investigations led to no definite conclusions on the part played by tuberculosis in silicosis, pulmonary tuberculosis was nevertheless a complication to reckon with, even in occupations where the silicosis appeared slowly. Moreover, the outlook for persons suffering from silicosis and "open" tuberculosis is almost uniformly bad, although silicotic and tuberculous lesions might coexist without apparently exerting any influence on each other.

Discussing clinical investigations, in the second part of the monograph, Bruce concludes that, although the radiographical appearances in the various occupations are similar, nevertheless certain characteristic differences indicate the type of work causing the silicosis. By means of bronchography he demonstrated frequent bronchial changes in silicosis Stage 3, chiefly in the anterior branches. Similarly, spontaneous pneumothorax was found to complicate advanced silicosis, the pneumothorax being presumably itself a complication of the emphysema that follows fibrosis. Even when bilateral, spontaneous pneumothorax may be symptomless and disappear; but it may recur, and in general the outlook for the silicotic is worse. Bruce concludes that respiratory insufficiency in silicosis is caused by the emphysema that develops in the course of the disease; but there are certain differences between this and the "usual" emphysema.

THE HALF-YEARLY INDEXES

The usual half-yearly indexes to the *Journal* and to the *Supplement* have been printed. They will, however, not be issued with all copies of the *Journal*, but only to those readers who ask for them. Any member or subscriber who wishes to have one or both of the indexes can obtain what he wants, post free, by sending a postcard notifying his desire to the Accountant, British Medical Association House, Tavistock Square, W.C.1. Those wishing to receive the indexes regularly as published should intimate this.

THE PASTEURIZATION OF MILK*

BY

G. S. WILSON, M.D., F.R.C.P. D.P.H.

Professor of Bacteriology as applied to Hygiene, London School of Hygiene and Tropical Medicine

It is frankly impossible, in the space allowed, to put forward the full case for compulsory pasteurization of milk or to answer the numerous objections that have been raised against it. A few years ago, owing to insufficient evidence, scientific opinion was divided on pasteurization. Since then numerous experiments have been carried out in the laboratory and in the field, the results of which show that pasteurization brings about no detectable change of any significance in the nutritive value of the milk. Objections are frequently raised to it on pseudo-scientific grounds, but the real objection in the past has been financial, and has come from the producer-retailers. Before the war farmers of this kind received both the producers' and the distributors' profit; if they had been compelled to pasteurize their milk themselves, or to arrange for its pasteurization elsewhere, their receipts would have been slightly diminished. Now, however, when the Milk Marketing Board buys all their milk and sells it to them again at a uniform price, whether raw or pasteurized, this financial objection no longer has any weight.

In the following brief summary statements will have to be made without qualification, and without providing the evidence on which they are based. Those who are anxious for further information may be referred to a report which I made to the Ministry of Health and which has been published recently in book form.†

Question 1: Why is there a Milk Problem?

Answer.—Cows' milk is a food of exceptional value for the growing child. It contains a well-balanced mixture of fat, carbohydrate, and first-class protein; it is rich in mineral salts, especially calcium and phosphorus; and it contains important vitamins. On the other hand, it is more often infected with pathogenic bacteria and more likely to give rise to disease than any other common article of our dietary. Hence arises the double problem of how to improve the nutritional status of the young without spreading milk-borne disease, and how to abolish milk-borne disease without lowering nutritional standards.

Question 2: To What Extent is Raw Milk infected with Pathogenic Bacteria?

Answer.—About 5 to 10% of farms in this country are sending out milk containing tubercle bacilli; about 20 to 40% *Brucella abortus*; and a much higher proportion mastitis streptococci, which, though not usually infective to man, may cause undesirable changes in the milk. "Accredited" milk appears to be as heavily infected with tubercle bacilli as ungraded milk; and tuberculin-tested (T.T.) milk is just as heavily infected with *Br. abortus* as ungraded milk, if not more so. Bulked milk reaching our large towns usually contains all three organisms—namely, tubercle bacilli, *Br. abortus*, and mastitis streptococci. Occasionally milk becomes infected with other organisms, such as scarlet fever streptococci, diphtheria bacilli, and bacilli of the typhoid, paratyphoid, food-poisoning, and dysentery groups.

Question 3: How do Pathogenic Organisms reach the Milk?

Answer.—Tubercle bacilli, *Br. abortus*, and mastitis streptococci, from the cow's udder; organisms of the typhoid, paratyphoid, food-poisoning, and dysentery groups, either from the infected fingers of those handling the milk or from water used for washing the cows' udders, cleaning the milk utensils, or watering the milk; scarlet fever streptococci and diphtheria bacilli, from the cough-spray of the milker or from the infected udder of the cow.

Question 4: How Much Disease is Raw Milk responsible for in the Human Population?

Answer.—In England and Wales about 1,500 to 2,000 deaths a year from tuberculosis of bovine origin; 400 to 500 cases of undulant fever; occasional outbreaks of scarlet fever, septic sore throat, diphtheria, typhoid fever, paratyphoid fever, dysentery, and acute gastro-enteritis. It is known that during the years 1912 to 1937 there were at least 113 outbreaks of epidemic disease in Great Britain, affecting about 14,000 persons. During the same time about 65,000 persons in England and Wales died of tuberculosis of bovine origin, and an unascertained number, probably several thousands, suffered from undulant fever contracted through milk. If epidemic summer diarrhoea in infants under 2 years of age is included, some of the deaths during this period, which in England and Wales amounted to 190,000, must be added to this total.

Question 5: Why do Some Practitioners Belittle or Deny the Existence of Milk-borne Tuberculosis?

Answer.—Because their clinical training makes them think in terms of the individual rather than of the herd. They do not realize that if every practitioner saw a case only once in 5 years there would be 8,000 cases annually in England and Wales.

Question 6: How can Milk be Rendered Safe for Human Consumption?

Answer.—Tuberculosis and undulant fever could be avoided by the establishment of tuberculin-tested and abortion-free herds. Diseases of the typhoid, paratyphoid, food-poisoning, and dysentery groups might be diminished to some extent by a rigid clinical and bacteriological supervision of all those employed in handling milk, and by the provision to all farms and dairy establishments of a safe water supply. Since about 40% of the cattle in this country react to the tuberculin test, and about one in every 200 cows is excreting tubercle bacilli in its milk, the establishment of sufficient T.T. herds to provide liquid milk for the human population would be an enormous task. It may be pointed out that in the United States, where a campaign for the eradication of tuberculosis among cattle was started in 1917, an initial tuberculin-positive rate of 4% was reduced by 1939 to a rate of about 0.5%, at a cost of $260,000,000. In this country we should have to start with a rate ten times as high, and with herds far more closely packed together than in the States. The control of contagious abortion, which is widespread in cattle, presents an almost insuperable problem, as does that of mastitis. Control of the human personnel handling the milk is not reliable, and even if it were it would create so many administrative difficulties as to be unworkable. The only practicable method at present of ensuring that the human population is supplied with milk free from pathogenic organisms is by some form of heat treatment, of which pasteurization, if carried out under proper conditions, is undoubtedly the most satisfactory.

Question 7: What is Pasteurization?

Answer.—Pasteurization is a loose term applied to several forms of heat treatment of milk. In this country, however, only two methods of pasteurization are officially allowed—namely, pasteurization by the holder method and pasteurization by the high-temperature short-time (H.T.S.T.) method. In the holder method the milk must be retained at a temperature of not less than 145° F. and not more than 150° F. for at least 30 minutes, and then cooled to a temperature of not higher than 55° F. The milk must *not* be heated more than once. The processing plant must be provided with indicating and recording thermometers, and temperature records must be preserved for a period of not less than 1 month. In the H.T.S.T. method the milk must be retained at a temperature of not less than 162° F. for at least 15 seconds, in an apparatus that is thermostatically controlled and provided with an automatic device to divert the flow of any milk which has not been so treated. The milk must then be cooled as under the holder process. The efficiency of either method may be tested by means of the phosphatase reaction. The enzyme phosphatase is destroyed by a time-temperature combination slightly higher than that necessary to destroy tubercle bacilli. Milk, therefore, in which the phosphatase test is negative can be regarded for all practical purposes as free from pathogenic organisms.

Question 8: What Effect has Pasteurization on the Properties and Nutritive Value of Milk?

Answer.—About 5% of the lactalbumin is coagulated; the coagulation time by rennin is lengthened, but the casein clot formed consists of finer particles and is of a more open texture: there is a diminution of about 5% in the soluble calcium and phosphorus; there may be some loss of iodine through volatilization; about 10% of vitamin B_1 is destroyed, and about 20% of vitamin C; the flavour of the milk is somewhat altered owing to the removal of volatile products from the raw milk, but in properly pasteurized milk the acquirement of a cooked flavour is practically negligible and cannot be distinguished except by a very few persons; the keeping quality of the milk is increased considerably. Against these positive changes may be set a number of negative findings. Observations on rats, mice, calves, and children have failed to reveal any change in the biological value and digestibility of the protein, in the availability of the calcium and phosphorus, in the amount of vitamin

A or D, or in the total energy or nutritive value of the milk for the growing animal.

Question 9: Does Pasteurization Destroy Pathogenic Organisms in the Milk?

Answer.—The tubercle bacillus is destroyed by a temperature of 138° F. in 30 minutes, of 145° F. in 5 to 10 minutes, of 150° F. in 2 to 5 minutes, and of 160° F. in 12 seconds. It will be seen that there is an ample margin of safety in the time–temperature combination laid down for the holder method, and a fair margin of safety in that laid down for the H.T.S.T. method of pasteurization. Other pathogenic organisms—with the exception of *Staphylococcus aureus*, which is not pathogenic by the mouth—are more susceptible to heat than the tubercle bacillus, so that their survival in pasteurized milk is improbable.

Question 10: Is Pasteurization Antagonistic to Clean-Milk Production?

Answer.—It is not sufficiently appreciated that the quality of the pasteurized product depends to a considerable extent on the cleanliness of the raw milk. It is therefore to the advantage of the large dairy companies practising pasteurization to obtain the highest quality of raw milk. To most farmers it is immaterial whether their milk is pasteurized or not. Their real motive for improving the cleanliness of their supply is financial. The operation of the accredited-milk scheme in this country showed that a bonus payment of 1d. a gallon for accredited milk led to an enormous increase in the number of registered suppliers, in spite of the fact that a large part of the milk so produced was being taken to London and the large towns to be pasteurized. It is sometimes objected that a farmer who has taken considerable trouble to produce clean milk will be disheartened if he finds that his milk is to be mixed with that of a lower standard of cleanliness from other farmers. Perhaps this is true, but it is an argument not against pasteurization but against the bulking of milk.

Question 11: Is Pasteurization Antagonistic to the Eradication of Diseased Animals from Milking Herds?

Answer.—As with clean-milk production, the stimulus to eradicate disease is almost purely financial, and is unaffected by the subsequent history of the milk. This has been amply shown by the success of the Tuberculosis (Attested Herds) Scheme, in which financial support was given to the producer who was anxious to eradicate tuberculosis from his herd. It is also borne out by the experience of the United States. In 1936, for example, no less than 99.8% of raw milk and 99.2% of pasteurized milk distributed in towns of 1,000 inhabitants and over was derived from T.T. herds. The two figures are so nearly identical as to lend no colour to the view that pasteurization retards the process of disease eradication.

Question 12: How Often is Pasteurization Inefficient?

Answer.—The term "pasteurized" is often applied erroneously to any heat-treated milk, not solely to milk that has been heat-treated in a licensed plant by one or other of the two methods laid down by the Ministry of Health. Many of the statements that pasteurized milk has been found to contain tubercle bacilli are incorrect if the word "pasteurized" is limited, as it should be, to officially pasteurized milk. Stringent requirements are exacted under the Milk (Special Designations) Orders of 1936 and 1938. In addition we have now a reliable test—the phosphatase test—for determining whether or not the milk has been adequately heat-treated. The proportion of inefficiently pasteurized milk is therefore much less than ten years ago. Examination of 1,439 samples of pasteurized milk taken during 1934 to 1936 in London, Manchester, Sheffield, and Liverpool failed to reveal living tubercle bacilli in a single sample, in spite of the fact that the raw supply was often infected. It is not denied that the record of small dairies may be less satisfactory than that of the larger dairies supplying our great cities, but if compulsory pasteurization was introduced more thorough supervision would be exercised over these smaller plants. Admittedly, owing to some undetected fault in the plant or to some human error, the milk may at times be inefficiently heated; but there is no more reason to condemn pasteurization on this account than there is to condemn railway transport because of the occasional failure of the signal system.

Question 13: Does the Consumption of Raw Infected Milk in Childhood Protect against Pulmonary Tuberculosis in Adult Life?

Answer.—Though some doctors believe this to be true, there is no reliable evidence in its support. Those who do advocate the consumption of raw infected milk fail to realize that what they are recommending is a method of indiscriminate vaccination with living tubercle bacilli in the hope that, by a process of natural selection, the survivors will be more resistant in later life to invasion by the human tubercle bacillus. Against what other disease, it may be asked, would a method of vaccination be tolerated that is known to demand at present the sacrifice of 1,500 to 2,000 lives a year?

Conclusion

Cleanliness of production is no safeguard against tuberculosis or contagious abortion in the cows; and T.T. milk is just as exposed as ungraded milk to infection from human sources. Though the ultimate ideal may be clean milk produced from disease-free herds and protected from human contamination, there is no other immediate practical solution to the problem of supplying safe milk to the public but pasteurization. Whether we like it or not, the logic of the case is inexorable.

EXPERIENCES IN A MILITARY HOSPITAL IN FREE CHINA

BY

H. T. LAYCOCK, M.B., F.R.C.S.

Surgeon, Friends' Ambulance Unit in China

In February and March, 1942, I had the strange experience of doing surgery in a military hospital in Kiangsi Province, in S.E. China. To reach this area it was necessary to make an overland journey of about 2,500 miles from Rangoon.

K. is a large Chinese city, the foreign residents of which are practically limited to two small mission communities. Several widely differing dialects are spoken, so there are formidable obstacles for the linguistic amateur. The nearest battle front is several hundred miles away in N. Kiangsi. The hospital in which I lived had 100 beds, a primitive operating theatre and laboratory, but no *x*-ray department. There were a few civilian victims of a recent air raid, and the other cases were all of wounded soldiers. There was no one practising surgery when I arrived, nor was there at the military hospital of 600 beds outside the city. I was received with great cordiality by the medical staff and by the local military commander, and was invited to help myself freely to surgical material from both institutions. I was further assured that when I had finished with these there were 4 more military "hospitals" waiting for me at greater distances. I use inverted commas advisedly because it requires some imagination to describe as hospitals some of the dumping-grounds in which many Chinese wounded soldiers develop their chronic lesions.

Medical and Nursing Staff

Our hospital was relatively good. It had been built up by the New Life Medical Movement, founded at considerable sacrifice by a group of doctors who gave up lucrative practices in the occupied areas in order to help Free China. The staff consisted of 3 doctors, of whom 2 had good qualifications and a knowledge of English. The third, alas! had neither. China has some excellent medical schools, but in others the qualifying standard is a low one, perhaps comparable to that required of a sub-assistant surgeon in India. A difference is that in China the holder is not debarred, if he can pull the necessary strings, from holding the most senior posts in hospitals. There were 7 nurses, of whom 2 were well trained, while the rest tried to make up for their amateur status by their infectious enthusiasm. There was unfortunately no system of night nurses, and from 8 p.m. until 8 a.m. the patients were at the mercy of a number of nondescript "boys," who were as likely to consign to perdition anyone who complained as to fetch help. On one occasion one of these "boys" showed a deplorable complacency in the presence of secondary haemorrhage.

Types of Wounds

The military patients came from various battle areas, especially from that around Changsha. All were more or less chronically disabled, and the majority had unhealed wounds of from 6 months to 4 years' duration. These cases of unhealed wounds fell into 3 classes. In the largest (45%) there was a sinus, or sinuses, connected with chronic osteomyelitis and/or a foreign body. I had no *x*-ray apparatus to guide me, but found in nearly every case that exploration was justified by the results. A typical case was that of a soldier, aged 24, wounded 3 years before. He said he had had 9 operations, presumably curettings, during this time. He had a completely stiff ankle associated with 3 sinuses. I explored a cavity in his tarsus and removed a large piece of shrapnel, which gave him great satisfaction. In spite of considerable opposition I introduced closed-plaster therapy in K. It was very difficult to convince the Chinese staff and patients that an offensive odour was no cause for alarm.

The other big group of patients with unhealed wounds (40%) had leg ulcers initiated by trauma and apparently maintained by syphilis, malnutrition, and lack of rest. Some of these were the largest I had ever seen; some extended the whole length of the tibia; others completely encircled the leg, often deeply involving the calf muscles. Many were associated with a fixed equinus. We had no potassium iodide and no organic arsenical preparations (in Kiangsi N.A.B. cost 120 dollars—about £1 10s.—per ampoule!). Rejecting as hopeless the very large ulcers just mentioned, I tackled the smaller ones by excision of the edges and curetting the unhealthy granulations of the base. For this the Chinese do not seem to feel the need for anaesthesia. A week or so later the areas so prepared were treated with pinch grafts. The results were uniformly good, which was surprising, especially as there was little discipline in the place and it was difficult to persuade the patients to stay in bed.

The remaining cases (15%) had not healed for a variety of reasons. For example, there was a bronchial fistula, a small bowel fistula, a subphrenic abscess following an untreated bullet wound of the abdomen which was discharging on the surface though drainage was inadequate, a bullet wound of the perineum with multiple urinary fistulae, a sinus connected with an infected extradural haematoma, and so on.

"Chronic" Disablement

Some of these young soldiers were pathetically eager for treatment, but many were quite content to remain chronically disabled. On most Chinese battlefields medical services are conspicuously absent, and it is left to the wounded man to extricate himself if he can. If he is seriously wounded he does not get away. With a less serious injury he does not get treatment in the early stages, and the journey to hospital takes so long that his disability is likely to have passed into a chronic state before he does arrive. Even in hospital he is most unlikely to receive radical treatment. In the large base hospital outside K. there were 600 patients. No notes were kept and practically no surgery was done. The general standard of the place is illustrated by the fact that many of the patients chose to walk 5 miles into the city each day in order to have their dressings done either at our hospital or at one of the mission stations. Perhaps the chief reason why most of the patients showed no eagerness to get well was that "occupational therapy" was available. This meant that the men were allowed to make string and to be paid for doing so. By getting up at 5.0 a.m. and working hard all day, as many of them did, a man could earn as much in one day as he would earn in a week at the front. Additional attractions were regular, if inadequate, meals while in hospital and access to the local cinema, so that the complacency with which they came to regard themselves as incurable was easy to understand. One man, aged 28, gave an indefinite history of a wound in the leg healed months before. For nearly a year he had walked about the city with one knee full-flexed, using crutches. When I gave him a spinal anaesthetic and demonstrated to his companions that both his legs were normal he was much upset and they were vastly amused.

STERILIZATION OF SULPHANILAMIDE POWDER

The Medical Research Council recently called a conference, which was attended by clinicians, bacteriologists, and representatives of the Association of British Chemical Manufacturers, to consider methods of sterilization of sulphanilamide powder for local application. The following is a summary of the findings of the conference.

The report[1] of a fatal case of tetanus which was possibly due to infection from the container of a sulphonamide powder applied locally emphasizes the desirability of the practice, already adopted in the United States, by which all sulphonamide preparations intended for topical application are marketed ready sterilized in sterile containers. It has been shown that if sulphanilamide powder contaminated with tetanus spores is implanted in the tissues of animals, the presence of the drug does not prevent the development of tetanus.[2] An account by Dr. John H. Brewer of the procedure used by Hynson, Westcott, and Dunning in America for the large-scale sterilization of sulphanilamide powder in 5-g. packages ready for use was published with a covering letter from Lieut.-Col. Perrin H. Long in the *Lancet*, Sept. 12, 1942 (p. 322). At a conference held in Nov., 1942, between representatives of the Medical Research Council and the Association of British Chemical Manufacturers it was agreed that the Hynson, Westcott, and Dunning procedure was suitable for adoption also by British manufacturers of sulphanilamide powder, and that the powder thus sterilized should be issued in sterile packets each containing 5 g.

Since, however, this recommendation must inevitably take some time to put into full effect, and it would not, in any event, apply to existing stocks of the powder held in hospitals and at aid posts, the conference proceeded also to consider suitable methods for the small-scale sterilization of sulphanilamide powder. It was considered probable that lack of uniformity in the results reported by different investigators with a particular sterilizing method which, on theoretical grounds, should have proved satisfactory was attributable to minor variations in technique, and, more especially, to the known variability of different commercial preparations of sulphanilamide powder with regard to chemical purity and physical properties. Thus, it was pointed out that thermostatic control of a hot-air oven, without a check on the actual temperature of the powder itself, was insufficient to ensure that the temperature aimed at for sterilization was in fact being applied; careful control in this respect, by means of thermocouples in certain of the packages, was one of the notable features of the procedure used by Hynson, Westcott, and Dunning for large-scale sterilization. Caking and discoloration of the powder on heating might depend upon a number of factors, including the degree of purity, the moisture content, and the particle size. Very fine powders tended to cake, and the powder found satisfactory for large-scale issue in the United States was standardized at a 40-80 mesh. It was agreed that a sulphanilamide powder to be satisfactory for local use after sterilization should not show more than a slight discoloration after heating at 150° C. for one hour.

Small-scale Processes for Hospitals

For the small-scale sterilization of sulphanilamide powder in hospitals, etc., the following alternative procedures were recommended:

(A) Dry heat maintained at 150° C. for one hour in a paraffin bath, with the technique proposed by H. Berry[3] as follows: "Use dry sterile cotton-wool-plugged test-tubes (5 inches × 3/4 inch or smaller diameter). Half fill them with the dry powdered substance, using a powder funnel. Flame the upper portion of the tubes and replug with the sterile plugs. Immerse to within one inch of the tops of the tubes in a liquid paraffin oil bath and maintain at 150° C. for one hour. If the tubes are to be stored the plugs should be covered with cellophane or paper."

(B) Dry heat maintained at 150° C. for one hour in an electric oven, with precautions to ensure even heating throughout.

(C) Autoclaving in a dressings sterilizer by the technique and with the precautions proposed by W. J. Buckland[4] as follows: "An autoclave with vacuum drying attachment (dressing sterilizer) is used and the container is a dry boiling-tube plugged with non-absorbent wool. The boiling-tube must be thoroughly dried, if possible in a hot-air oven. (1) The jacket pressure of the sterilizer should be ready at a pressure of 20 to 30 lb. (2) Allow steam at 20 lb. into the empty closed chamber of the autoclave and leave for five minutes. (3) Using the appropriate valves clear chamber of all steam and condensed water. This process has heated the chamber, and the boiling-tubes, loosely plugged with non-absorbent wool and containing the powder (in 5- or 10-g. batches), are now placed in it. They should be placed on their sides, with the powder spread over their full length, giving a thinner mass for the steam to penetrate. (4) Leave the tubes for 15 minutes in the hot chamber; this heats tubes and contents sufficiently to prevent condensation inside and on the powder. (5) Autoclave at 15 lb. for half an hour. (6) Clear the chamber of steam and any condensed water quickly, and allow vacuum of 10 to 15 inches for 15 minutes. (7) Remove tubes from autoclave, place a tight sterile plug of non-absorbent wool on the top of the one already in, and cap tubes with a suitable paper—preferably cellophane. Caking does not occur. If apparent caking is observed, it is only present while the powder is still hot, and when cool a tap on the side of the tube is all that is necessary to show the sterile preparation to be the desired soft powder."

A proviso should be added with each of these recommendations that a sulphanilamide powder to be satisfactory for local application should not cake or be more than slightly discoloured with any of the techniques proposed.

The recommendations of the conference related only to sulphanilamide powder, as the sulphonamide preparation most frequently applied locally. It may be mentioned, however, that the paraffin bath technique described by Berry[3] is recommended by the author as being suitable also for the sterilization of sulphathiazole powder in hospital practice.

SALARIES AND EMOLUMENTS OF NURSES

FIRST REPORT OF RUSHCLIFFE COMMITTEE

In November, 1941, the Minister of Health appointed a Nurses' Salaries Committee, under the chairmanship of Lord Rushcliffe, to draw up agreed scales of salaries and emoluments for State-registered nurses employed in hospitals in England and Wales. The committee's first report, which has now been issued as a Command Paper,[1] deals with female nurses other than those employed in mental hospitals. Further reports affecting nurses in the public health service, district nurses, and male nurses will be issued later, and a separate committee, also under the chairmanship of Lord Rushcliffe, is considering midwives' salaries.

The work of the committee has been done by two panels, one nominated by organizations representing nurses and the other by organizations representing employers of nurses. In approaching their problems the committee has been guided not only by consideration of what is a fair and appropriate remuneration for a nurse, having regard to her status and responsibilities, but also by the importance of attracting the right type of person to the profession. Further, the number of trained nurses qualifying at the present time is not enough to satisfy growing demands or to make good the wastage caused by nurses giving up their work for personal reasons such as marriage. "Notwithstanding the many demands on woman-power at the present time," the report states, "an increased flow of suitable student nurses into hospitals should be encouraged. . . . What is required as a stimulus to recruitment is that the prospect of the nurse after training, in senior as well as junior posts, should be equitable and attractive."

Present Proposals

The chief recommendation is, therefore, that there should be national salary scales covering every grade of nursing staff in every type of hospital (except mental hospitals). The report sets out what these graded salaries should be, and at the same time fixes for each category of nurse what is regarded as a reasonable valuation of the emoluments (board, residence, and laundry), in terms of cash, this amount to be the standardized value for superannuation purposes. The salaries for matrons and assistant matrons are to vary according to the type and size of the hospital. The matron's salary in a hospital of 500 or more beds approved by the General Nursing Council for complete training in general nursing, sick children's nursing, or fever nursing will range from £450 to £700 (total value of salary and emoluments £650 to £900). For nurses from student status to that of qualified senior sister tutor the new salaries will be as follows:

	Scales of Annual Salary	Total Value of Salary and Emoluments
Student nurse	First year, £40, second, £45; third, £50; fourth year (before State registration), £60, fourth, after State registration (if on four years' contract), £70	£115–£145
Staff nurse (on general part of State register)	£100, rising by £5 a year to £140	£190–£230
Ward sister	£130, rising by £10 a year to £180; with one additional increment of £20 after ten years' service as ward sister	£230–£300
Qualified senior sister tutor (in charge of one or more others)	£260, rising by £15 a year to £350	£380–£470

Slightly higher rates of pay are proposed for nursing staff up to and including sisters in sanatoria and tuberculosis hospitals, because "of the special difficulty in staffing that prevails."

Other Recommendations

The report makes some recommendations to the General Nursing Council on the training of sister tutors. It suggests that the council should standardize the training, as the Central Midwives Board has that for midwives—that is, it should draw up a curriculum, prescribe rules of admission including the amount of experience that candidates should have had, and approve institutions for training purposes. It is further recommended that an educational grant should be made by the Ministry of Health to enable suitable nurses who otherwise could not afford it to train as sister tutors. Sanatoria should be encouraged to become training schools for those taking up the nursing of cases of tuberculosis and certain respiratory diseases, and it is suggested that there should be a supplementary part of the State register for such nurses, though the use of the term "tuberculosis" in the title should be avoided.

The new salaries, which are to come into operation on April 1, are based on the general establishment, as soon as conditions permit, of a 96-hour fortnight, day or night. In the committee's opinion all nurses, including students, should have at least one complete day off duty a week and should have 28 days' holiday with pay each leave year. It is not desirable that there should be nursing staff doing permanent night duty; the maximum continuous periods of night duty should be six months for sisters and staff nurses and three months for student nurses. All nurses should be provided with uniform free of cost, and the practice at some hospitals of charging a fee from students at the beginning of their training should be stopped. Finally the report makes recommendations about sick pay, and also suggests that all nursing staff at sanatoria and tuberculosis hospitals, other than matrons or assistant matrons, should have free travel twice a week to the nearest centre of population.

The Minister of Health, announcing the publication of the report in the House of Commons on Feb. 11, stated it was estimated that the total additional cost of these recommendations would be between £1,500,000 and £2,000,000 a year, and he was informing local and voluntary hospital authorities that the Government was prepared to pay 50% of any increased expenditure incurred in giving effect to these recommendations.

THE POSITION IN SCOTLAND

The corresponding committee in Scotland, under the chairmanship of Prof. T. M. Taylor, has also recommended national salary scales, the salaries suggested for student nurses and for ward sisters being the same as for similar personnel in England and Wales, except that sisters reach their maximum in 15 years. In the case of staff nurses in Scotland the maximum salary is to be lower but the increments larger—i.e., £100 a year rising by £10 to £120; and a qualified senior sister tutor in charge of two or more others will receive £250 with annual increments of £10, but her maximum has not yet been agreed. As in England and Wales the salaries of all matrons and assistant matrons will vary with the size and type of hospital—for example, the assistant matron of a hospital of over 300 but under 500 beds will receive a salary of £240 rising by £15 a year to £285 (emoluments £120); the starting salary of a matron of a similar hospital will be £350, with annual increments of £125, but here again the maximum has not yet been decided.

The two reports agree on such questions as the 96-hour fortnight, night duty, free uniform, and the abolition of entrance fees for students. Sick pay, annual leave, and off-duty time are still being considered. The Scottish report, however, goes further than the English one and makes recommendations about the salaries of midwives, health visitors, and district nurses. Subject to certain adjustments for qualifications and duties undertaken, the salaries of domiciliary midwives, health visitors, and district nurses will normally start at £250 a year and rise to £320 in the 15th year. Where board and residence are provided the salary will be £100 less.

Local and hospital authorities in Scotland have received the same assurance as those in England and Wales that the Government will pay 50% of any increased expenditure these improved salary scales will mean.

THE ROYAL COLLEGE OF SURGEONS

The Scientific Report of the Royal College of Surgeons of England for the year 1941–2 records the first steps in the restoration of the College Museum. Gifts from individuals and institutions, and offers of assistance from all over the English-speaking world, are laying the foundations of the new collections. Although relics of Hunter and Cheselden, Paget and Shattock have been lost for ever, these new collections in their own way will be equally historic. Specimens from Melbourne, Sydney, and Wellington will share the same shelves as those from Edinburgh and Manchester, Colombo and Capetown, Chicago and Montreal. They will be symbols of united purpose in a common cause and tributes to the common tradition of Hunter and Lister.

During the year the Research Laboratories have continued to make fundamental contributions to our knowledge of the effects of haemorrhage and transfusions. Articles on these researches appeared in this *Journal* during 1942. It is unfortunate that the demands of the Services prevent fuller use being made of the research facilities at the College. There is no lack of problems of immediate practical value, but Service men and women well trained and interested in research problems often lack the facilities to carry on their investigations. Perhaps some means can be found of seconding them for limited periods to laboratories which have the facilities they require.

A SAFE MILK SUPPLY

B.M.A. Deputation to the Minister of Food

On May 18 the British Medical Association led a large and influential deputation to the Minister of Food (Rt. Hon. Lord Woolton) to urge the need for complete and efficient pasteurization of milk. The deputation included representatives of the Royal Colleges, the National Association for the Prevention of Tuberculosis, the Joint Tuberculosis Council, the British Paediatric Association, the People's League of Health, and other bodies. With the Minister was Miss Florence Horsbrugh, M.P., Parliamentary Secretary to the Ministry of Health.

Prof. R. M. F. PICKEN, Acting Chairman of the Council of the B.M.A., introduced the deputation by pointing out that there was no serious difference of opinion in the medical profession on the question of pasteurization; few questions in preventive medicine commanded so nearly complete unanimity. The Representative Body in 1936 agreed, with only one dissentient, "That only milk complying with the conditions required for the designation 'tuberculin tested' or 'pasteurized,' or preferably both, can safely be consumed without boiling." When the British Medical Association decided to embark on a campaign of medical publicity the first thing it did was to spend some thousands of pounds on advertising safe milk. In February, 1939, the Association led a deputation on the subject to the Ministers of Health and Agriculture. The Royal College of Physicians had recently passed a resolution advocating pasteurization. Seven years ago, when the British Medical Association gave qualified approval to "tuberculin tested" milk in the raw state, it did so in the hope that steps would be taken to improve the quality of milk in that respect, but in 1939 he believed that only 3% of the herds in this country were attested, and there had been no increase since then. There was no quick solution on those lines, and pasteurization was the only practicable safeguard which had no serious disadvantage. The problem had been intensified in wartime by the proper endeavour of the Ministry of Food to maintain milk production and to increase consumption among young children. The necessary redistribution of milk rounds took away from families the free choice of dairy, so that many who had been accustomed to buy safe milk had been transferred to dairies which could not supply it.

Prof. L. P. GARROD (St. Bartholomew's) said that tuberculosis was deplorably common among dairy cattle, and the percentage of samples of milk which contained some tubercle bacilli was between 5 and 10. One-third of the deaths from tuberculosis in children under 5 were due to the bovine organism; this meant 2,000 deaths a year, with, of course, a much larger incidence of invalidism and crippling. Another disease of the cow which was transmitted in milk was contagious abortion, producing in man a long and incapacitating fever; this was not very common, but some hundreds of cases occurred. Ordinary infectious diseases might also be conveyed by milk, commonly owing to contamination by the milker. He instanced the typhoid fever epidemic at Bournemouth in 1936. The only remedy was pasteurization. All bacteria concerned in producing these diseases were destroyed by a moderate degree of heat, far below boiling-point, applied for a short time. Pasteurization did not alter flavour. Admittedly it destroyed a certain amount of vitamin C, which could be made up in the form of fruit juice. The advocacy of pasteurization had been referred to as a policy of defeatism—the countenancing of the production of dirty, infected milk, and covering its defects by this additional process. That was a specious argument. There was no immediate prospect of eradicating tuberculosis from cattle—that would take a generation—and to guarantee that no person handling milk was a carrier of germs of disease would mean an impossibly rigid supervision of the whole personnel of the industry. Pasteurization must be recognized as the only complete safeguard, but it must be pasteurization carried out efficiently in accordance with standard regulations.

Dr. ALAN MONCRIEFF said that paediatricians were anxious about the possibility of infections of the alimentary tract which were traceable to dangerous milk. The adjective which should be stressed was "safe." Innumerable claims had been made for various grades of milk, but the grading system had dismally failed from a safety point of view. The term "T.T. milk" was most unfortunate. Even if tuberculosis were eradicated by getting rid of all infected cattle, the danger of other infections would remain. Only a special pasteurization process which could be easily controlled by tests seemed to give the guarantee of safety required. The question had been raised as to whether some immunity was lost by not drinking raw milk. There was no scientific evidence that raw milk conferred any sort of immunity. Even if it did, the price would be too high to pay. If inoculation against diphtheria involved 2,000 deaths a year—which was what bovine tuberculosis in young children involved—it would be difficult to maintain propaganda for inoculation.

Dr. D. S. SUTHERLAND said that during the last ten years between 1,200 and 1,800 samples of milk entering Manchester had been examined annually. The percentage of samples in which tubercle bacilli were found varied from 10.57 in 1933 to 7.12 in 1941. In the case of samples of pasteurized milk it was only during the last two years that any tubercle bacilli had been found at all, and then only to the extent of 1.11% and 0.45% of the samples, whereas the figures for samples of milk coming from tuberculin-tested herds had varied from 8.7% to 2.27%. The appearance of bacilli in pasteurized milk during the last two years was no reflection on pasteurization, but only on the way in which it was carried out during the war, with the withdrawal of skilled workers.

Prof. W. H. TYTLER, who represented the National Association for the Prevention of Tuberculosis, said that its council had unanimously recommended the extensive application of pasteurization. There still seemed to be an impression that the role of milk in causing tuberculosis in human beings was controversial, but in fact it was as well established as the case against the mosquito as the carrier of malaria. He also mentioned an investigation into the outbreak of meningitis in 1941 with a view to ascertaining whether there was an increase in the proportion of bovine infection, and whether this was traceable to milk or was due to the movements of evacuated children affecting a particular locality. The results were rather indefinite, but there was some suggestion that there was a relative as well as an absolute increase in the amount of bovine infection causing meningitis, and that milk was responsible for at least a part of the meningitic wave.

Sir ALFRED WEBB-JOHNSON said that he had thought it his duty as President of the Royal College of Surgeons to join the deputation because of the enormous importance of the prevention of surgical tuberculosis. A moral, if not a legal, responsibility attached to the Government as controllers of the organization and sale of milk to take adequate steps to prevent infection. Prof. HARRY PLATT (Manchester), Dr. J. A. STRUTHERS (M.O.H., Holborn), and Dr. HARLEY WILLIAMS also spoke in support of the objects of the deputation.

Dr. C. O. HAWTHORNE, speaking for the People's League of Health, said that the public was attracted and misled by the use of such terms as "clean" or "pure" milk; and even "accredited milk," which had received a certain amount of official countenance, did not escape reproach. The term he preferred was "safe milk," meaning pasteurized milk, which was the only label guaranteeing against infection. One factor to be borne in mind was the number of children who had been evacuated from towns, where they had mostly received pasteurized milk, to country districts where milk was not pasteurized. In these circumstances boiling ought to be emphasized as a means to the same end.

Lord Woolton's Reply

Lord WOOLTON expressed his gratitude to the deputation. He could not imagine a more influential one. He recognized fully the obligation of the Government to obtain a milk supply which could do no harm, or alternatively, if this was not possible, to issue instructions as to how people should obtain reasonable security in the process of drinking milk or giving it to their children. Miss Horsbrugh and he would report this conversation to their colleagues in the Government. He found it difficult to resist the weight of scientific and professional evidence which had been assembled. What the Government had the power to do was obvious, but it was of no use introducing legislation which was not effective. He was at present engaged in collecting all the necessary information regarding the available machinery and competent labour to undertake the work which would give to the public security on this question.

Correspondence

The B.M.A. and the Beveridge Report

SIR,—The B.M.A. is to be congratulated on its ready acceptance of Assumption B of the Beveridge report provided legislation on the lines of the whole report is carried through. However, if there are to be "comprehensive health and rehabilitation services for prevention and cure of disease and restoration for capacity for work available for all members of the community" at a standard rate, what inducement will there be for anyone to pay more than that rate for any part of the service? Or, looking at it the other way, if "the whole resources of modern medicine" are at the "disposal of every man, woman, and child in the country," what else will the medical profession have to offer anyone at any price?

The present National Health Insurance service is not comprehensive, and is not available to a large section of the community. Thus, theoretically at any rate, persons outside that service now pay for their own private treatment because that is the only way they can obtain medical benefits of any sort. But if the National Health Insurance service were open to everyone, and, in addition, were declared to provide "the whole resources of modern medicine," what inducement could there be for anyone to pay any more than was necessary to obtain such a service? On that very vital question hangs proviso (*b*) of the motion now under consideration by the B.M.A.

If the medical profession offers every citizen full medical services under the 100% proposal and at the same time announces that it is prepared to accept a higher rate of payment by private arrangement for the same services, the public must conclude either that we think it worth while to exploit the type of person who will pay £2 for what he can get for £1 or else that we are conniving at the suggestion that patients treated under the 100% proposal are not really "enjoying the whole resources of modern medicine" at all. There are no other alternatives, and either of these conclusions is equally disturbing to that sense of security and confidence that the whole Beveridge plan is designed to create.

The recipient of State service, particularly at times of severe illness, would wonder if a few shillings might induce the doctor to exert himself a little more, and the man who paid private fees would feel that he had the right to expect that "little more," in any case. You cannot offer a service or commodity at two different prices without suggesting that there are two different qualities available. The whole idea seems to embody all the evils of the tipping system and smack of a blatant commercialism which would lower the status of the medical profession for evermore. Even without admission of private practice doctors would still be free to accept tokens of gratitude. That in itself provides quite sufficient latitude for abuse without giving any open hint to the public that we have a "back room" and a "special welcome" for our more wealthy patrons.

Let the medical profession offer to "every man, woman, and child the whole resources of modern medicine" and see to it that every one in that profession is adequately paid for his services. Then set up no rival standards, but, by every possible means, induce every member of the community to believe that the best is always at his disposal, and that those who give it are satisfied that the community is paying them a fee worthy of their best efforts. Any Government could be relied upon to appreciate that to establish such confidence it was of prime importance that the just claims of the profession should be fully satisfied. See to it that this nation's medical services are so good that no patient or doctor feels that better can be obtained anywhere "for love or money." Let the public know that this, at least, is our endeavour from the outset, and that we are making no provision for nor are we permitting any other standard of service to be available to anyone.—I am, etc.,

Eye, Suffolk. J. SHACKLETON BAILEY.

SIR,—"The doctor must be the servant of his patient," you state in your leading article (Feb. 13, p. 193). Is this incompatible with his being the servant of the State? Your antithesis is surely false. The doctor, even if he were the servant of the State, would still in his own professional domain be his own master. He does not want to be the servant of his patient. He suffers from that too much already, and many patients think that they have only to whistle to make the doctor jump; and what is more, they have the power to do so, thanks to the isolationist and competitive atmosphere in which we work. So bad is this in some parts of the country in which I have practised that patients deliberately play off one doctor against another to obtain a reduction of fees.

It is time that the doctor was, professionally, captain of his own soul, and this he has the chance of being under a State Medical Service. No longer need his hand be forced by the ignorant, the capricious, and the dominating among his patients. In a wealthy town on the South Coast no fewer than 187 priority milk forms were received in one milk shop on the first morning of the priority scheme. One can draw one's own conclusions from that fact; they may be right or wrong.

As a profession we seem to get the worst of every bargain, and the portents would seem to indicate that we risk running true to form once again.—I am, etc.,

Hove G. LLEWELLYN DAVIES.

SIR,—The decision arrived at by the Special Representative Meeting and the Panel Conference summoned for March 31 will be momentous to the prestige of the medical profession and to the course of future negotiations. The resolutions on which these meetings will be called upon to vote are set out in the *Supplement* of Feb. 13 (p. 25), and we hope that every Division and Panel Committee will give serious consideration to the second proviso (*b*) which is recommended as a condition of co-operation. It runs as follows: "(*b*) That those members of the community who decide not to avail themselves in part or in whole of the benefits of the service open to them should not be precluded from obtaining the medical services they desire from doctors within the scheme, paying for such service privately, with the necessary safeguards to prevent abuse."

It may well be that the retention of some measure of private practice will be found desirable in the interests of the new medical service, and it will be the duty of the medical representatives conducting negotiations with the Government to watch the interests of the profession in this respect. But if we, as a profession, offer co-operation in the establishment of a comprehensive service we must surely put the efficiency of that service before all other considerations. To make our co-operation conditional on the retention of private practice, as proposed in proviso *b*, will lay us open to the charge by both the Government and the public that we are concerned primarily with the security of our own vested interests. The details of this new service have still to be worked out. To prejudice negotiations at this stage by the introduction of any conditions is surely undesirable if co-operation is to be obtained between all parties.

We hope, therefore, that both the Representative Meeting and the Panel Conference will vote unanimously for the deletion of proviso *b*.—I am, etc.,

J. W. E. CORY,
Hon Secretary, West Suffolk
Bury St Edmunds Division "Study Group"

SIR,—I protest strongly against the statement in your leading article (Feb. 13, p. 193) that the doctor must be the servant of his patient. This is a dangerous and invidious statement, especially as it has already been copied in the lay press. A doctor is the servant of his profession, and no man can serve two masters. Further, we are not all of the servant class.

No section of the community has more scope than ours for the exploitation of hypocrisy and dishonesty. And the fact that these have been so little exploited is one of the chief reasons why we have maintained our privileges and a certain respect throughout the ages. If, however, it is publicly decreed that we must accept the role of servant to our patients then servility must follow, while hypocrisy and dishonesty will soon be established as merely professional characteristics and perquisites.—I am, etc.,

New Buckenham, Norfolk. R. G. BLAIR.

A Member Resigns

SIR,—Your leading article (Jan. 30, p. 135) is unusual, alike in its choice of subject and in its treatment of that subject. The curious mixture of the self-assertive, the faintly deceptive, the slightly minatory, and the suddenly plaintive suggests a comparison—from which all right-minded B.M.A. members will instantly recoil—with the curious present-day gyrations of a certain totalitarian propaganda machine.

With your contention that many B.M.A. members are lukewarm in their support of the Association I am not at the moment concerned, true though it is in fact. It cannot, however, be doubted that Service members have had little or no voice in the planning of the future of our profession and, in the nature of things, this cannot, at the moment, be otherwise. The Secretary's account of his successful negotiations with the Director-General of the Army Medical Services, resulting in permission being granted to R.A.M.C. officers to record and transmit their views on medical planning, touches only the fringe of the subject. Such permission can be of value only to the R.A.M.C. officer serving in this country, and, in fact, its value is theoretical rather than practical. The R.A.M.C. officer, be he administrator, specialist, or humble general duty officer, is, contrary to popular belief, already fully occupied with the very necessary task of helping to win the war. So far as our armies over-seas are concerned, one hesitates to ponder the replies from colleagues in the jungles of Burma, the sands of Libya, or the mud of Tunisia to an inquiry on their views of the future of our profession. Such replies, we hazard, would be bright and brief, if not particularly brotherly. Incidentally, we are not told whether similar freedom to express their views has been accorded to our colleagues in the Royal Navy and the Royal Air Force.

Doubtless our naval friends, fighting their way round Murmansk in the teeth of the blizzard, and in the face of the unwelcome attentions of the Luftwaffe and the U-boat packs, are giving the matter their most serious consideration. Nor can we expect a carefully balanced judgment from the not inconsiderable number of our colleagues who are at the moment in enemy hands.

Your plea on behalf of a mythical centenarian covers only one side of the question. Every well-brought-up young man should be eager to profit from the advice of his elders, but it cannot be gainsaid that our venerable Nestors when talking to (or down to) their juniors are a little apt to dilate at length on the verdure of the fields of their youth and/or on the excellence of the Biblical injunction touching the matter of yokes and young shoulders. With particular reference to present, and to future, problems they tend to overlook the probability that post-war pastures will yield more thorns than grass, and that post-war yokes will be of a much heavier pattern than heretofore.

Planning now for the future of our profession is necessary, but the translation of the plans into action must be deferred until members of the profession, temporarily in the Forces, have returned home at the end of the war and have had time and opportunity to study the problem in all its aspects.—I am, etc.,

JOHN M. HENDERSON,
Major, R.A.M.C.

SIR,—I do not think the B.M.A. has ever made any serious attempt to find out why it is that seven out of every eight members are politically inarticulate. Does not this problem merit some attention at Headquarters? It is not enough for the Association to say that the machinery is there and that if members do not make use of it nothing more can be done.

The B.M.A., in appointing the Medical Planning Commission —without any mandate from its members—has assumed the responsibility of guiding the profession through the troublous times ahead. Very well then, is a C.O. who never leaves his office entitled to assume that his unit is a happy one because he never receives complaints from his personnel through the official channels? There is a reason for the apparent apathy of the average medical man towards his own political interests, but the Association will not find out what it is by sitting in Tavistock Square. I would suggest that "Centenarian" comes out into the Provinces and finds out for himself.

It is not that the ordinary doctor has no views on matters of vital importance to himself; it is that he cannot use the machinery provided to make those views known. Theoretically it should work very well, actually it does not, because a G.P. nowadays has no time to give to secretarial duties, Division meetings, visits to London, etc. Consultants and specialists can arrange their work to a large extent, but a G.P. is tied to the telephone in a way that is quite incredible to those who have not experienced it. And the ordinary G.P. represents two-thirds of the profession.

The A.R.M. is a clumsy and lazy way of canvassing the views of the profession. The political landscape changes from day to day; Representatives meet once or twice a year, and experience quickly shows a G.P. the futility of trying to put his views across through the official channels. No wonder he is exasperated into displays of the arrogance which so scandalizes "Centenarian." Let the Association take a lesson from the defence of Leningrad; during the siege Party members were in and out of the trenches day and night, encouraging, advising, and directing. They did not call men off work which they cannot possibly leave to hold meetings. The mountain will not go to Mahomet, and if Mahomet will not go to the mountain he will lose his status as a prophet. Association Representatives must contact the profession on the spot, and it is no good saying that it can't be done. Trade union officials and M.P.s do not find it impossible to contact their constituents.

G.P.s as a body are suspicious of the negotiations now proceeding; they are exasperated and may easily break away altogether. I forecast this eventuality in a letter to the *Journal* some months ago as the outcome of the appointment of the Medical Planning Commission. I should deplore this result as much as "Centenarian," and I should cordially agree with his expectation of being made a scapegoat.—I am, etc.,

Lancaster. C. J. STOCKER.

SIR,—I have often wanted to resign from the B.M.A. I have refrained because I considered that the head and not the heart was at fault; but how are you to remedy a mental defect in a corporation? You, Sir, claim that the B.M.A. merely represents its members' opinions. How can it represent some thousands of divergent ideas, especially when, as on most of the questions the last few years, which are basically financial, there are diametrically opposing groups of the "haves" and "have nots"?

Bacon observes that "truth is more likely to come out of error than out of confusion." Interpreted by Prof. Leonard Gamgee in his lectures: "The next best thing to being definitely right is being definitely wrong." Now, I do not advocate the Council acting rightly or wrongly in defiance of the members, but I do suggest that, given the very large agreement we have on very important minor matters—such as reasonable income, hours, facilities, etc., for medical men—it probably does not make much difference what major decisions are taken providing the Council does obtain a decision and act on it; but this would appear impossible when Representatives are sent from the local meetings with binding resolutions. They must come armed with the opinions they have formed at the local meetings but be prepared to formulate a policy of their own—i.e., of the Representative Meeting as a whole. How could Parliament carry on if each member could only vote on the majority instructions from his constituency?

As I would blame a clergyman for empty pews, so I would blame the B.M.A. (for the fault is too general for local blame) for lack of interest in its meetings. When a member can speak at the Divisional meeting knowing that even if his own resolution is not accepted it will bear some weight with his Representative, he will come to speak, but at present, unless he has exceptional and dangerous influence as a speaker, a man may justly say: "Why should I waste my time; the committee has everything cut and dried?" Finally, I would say that if this plan cannot be carried out, and if this stage of confusion is not to lead to an anaesthesia from which we wake to find that the Ministry of Health has removed not only our income but our independence, the only alternative is for the B.M.A. to remove our independence first, and then tell us exactly what we are to think and do.—I am, etc.,

Birmingham. W. BRIAN GOUGH.

SIR,—May I associate my name with those of your correspondents who are obviously dissatisfied with the present-day complacent attitude of the B.M.A.? I appreciate that we are ourselves largely to blame for not being more active members, but it is hard to attend meetings and follow the politics of the Association when the day is more than fully occupied with the professional side of one's life.

With post-war reconstruction and some form of State medicine imminent we must look to the Association to safeguard our interests—by interests I do not mean our pay, though this should be adequate and commensurate with our training, but our conditions of work and facilities for treating our patients. I am now referring to psychotherapy, which is in particular a long and exacting form of treatment. If this treatment is to become available for the quite large percentage of the population who are needing it, then it will have to be financed by the State; but how? And who will be responsible for advising the Minister of Health on these matters? Will there be a repetition of that state of affairs which was current after the last war, or will the present-day E.M.S. neurosis centres take over this responsibility?

It was while I was at one of these centres that I wrote two letters to the Editor, one for his own information and the other for publication, the former essentially dealing with the question of personnel and the unsatisfactory conditions at the centre where I was working. The latter was in response to a paper by Major Hadfield on war neurosis, and in this letter I was critical of the methods of recruitment and the general management of the neurotic soldier. As I had no acknowledgment of either of these letters, I concluded that I had touched on dangerous ground and that the B.M.A. was unwilling even to consider any criticism of Government procedure. So what of the future?—I am, etc.,

Bishops Stortford, Herts. D. N. HARDCASTLE.

*** In the *Journal* of May 18, 1940, the following editorial statement was made, and has since been repeated: "In view of the restrictions now imposed on the use of paper, and the increase in the rates of postage which came into operation on May 1, it will no longer be possible to acknowledge the receipt of letters and memoranda, etc., offered to the *British Medical Journal* for publication." Owing to heavy pressure on limited space it is possible to print only a selection of the large number of letters submitted for publication each week.—ED., *B.M.J.*

SIR,—May I take the liberty of congratulating you on your masterly exposition of the facts in your leading article "A Member Resigns"? I have seldom heard of such conceit and arrogance as shown in that member's letter. As a medical officer on active service in a fighting ship may I express the hope that the Service to which he belongs will in due course teach him manners. The B.M.A. is a boon, long may it live!—I am, etc.,

"NAVY."

Houses to Live In

SIR,—In your leading article entitled "Houses to Live In" (Jan. 30, p. 136) you review the memorandum on "Design of Dwelling Houses" drawn up by the Committee on Social and Preventive Medicine appointed by the Royal College of Physicians. In the course of this review it is stated: "The College believes it to be a sound principle not to segregate the tuberculous in colonies, but to have them in the general community, in houses in which at any rate one bedroom is favourably situated as regards access of sunlight and fresh air, and has special windows opening more widely than the usual pattern."

I doubt very much if the College as a whole believes anything of the sort. If the tuberculous, thus housed, never stirred outside their houses, there would be something to be said for this view; though how they would earn enough to pay the rent or to buy food I do not know. But if one assumes that these tuberculous people, who are to have special windows, are under the normal human necessity of finding work, is it suggested that they should work in the general community too, and travel to and from that work in public vehicles, which do not always have special windows?

Remembering that the Royal College would certainly not recommend this mode of life for sufferers from leprosy—a disease no more infectious and certainly less fatal than tuberculosis—I cannot think that it is recommended for the tuberculous; and I would venture to suggest that the Royal College might welcome an opportunity of dissociating itself from the somewhat eccentric belief which is attributed to it in the paragraph quoted. It is at any rate in strange conflict with the recent M.R.C. Report on Tuberculosis in Wartime.—I am, etc.,

London, W.1. W. LANGDON-BROWN.

*** The relevant section (p. 15) of the report of the College reads as follows:

> "(1) *Tuberculous Persons.*—A number of progressive communities in England and Wales have given special consideration to the needs of the tuberculous in their housing schemes and the College believe that this principle is sound and deserves to be widely extended. In their view, however, it is not desirable to segregate tuberculous patients under any sort of colony conditions. They should be housed in the general community but subject to certain special safeguards. It is of great importance that, where a reduction of rent for tuberculous patients is permitted, or in the letting of houses to such patients, they should be subject to the following conditions of tenure:
>
> "(*a*) That the patient and his family agree to accept regular clinical supervision by attendance at a tuberculous clinic or such other arrangements as the Medical Officer of Health may require.
>
> "(*b*) That the family agree to regular visitation by the health visitor and to accept such measures of protection as the health visitor may suggest—e.g., the occupation of a separate room by the patient.
>
> "It is neither necessary nor desirable to make these houses conspicuous, but they should be placed in such a way that one bedroom, at any rate, is favourably situated as regards access of sunlight and fresh air. Arrangements can also be made for the provision of a special type of window which can be opened much more widely than the usual pattern. Nothing should be done, however, to mark out such families as infectious persons and so give them an unenviable place in the general community."

Dietetics of Pregnancy

SIR,—Those who do not refer to the reports of the Toronto experiment, that of the People's League of Health, and that of the meeting at the Royal Society of Medicine may be misled by Mr. R. B. Fisher's letter (Jan. 30, p. 145) on the effects of diet in pregnancy. Had he been content to criticize the faults of the papers of the Toronto workers and the uncritical enthusiasm of the writer of the leading article of Jan. 2 he would have done useful service. But he has gone on to draw conclusions without presenting or considering the more satisfactory evidence of the Toronto workers. For example, they give in both their papers the clinical rating, at various stages of pregnancy, by an obstetrician who did not know to which group each patient belonged; in the second paper they give the percentage, in each group, who had no complications. If these data had not been given, Mr. Fisher's criticism that there is no way of telling how many patients exhibited complications would be justified. The average duration of labour was five hours shorter in the group whose diet was supplemented; 86% of the women in this group were suckling their babies at six weeks after delivery, as compared with 59 of the poor-diet group. These differences in favour of the supplemented group may not be significant in view of the smallness of the groups, but they cannot be ignored.

Mr. Fisher bases an argument on one of the meanings given to the word "miscarriage" in this country. However, Toronto is not in this country, and the *Journal of Nutrition* and the *Canadian Medical Association Journal*, in which the work was reported, are not English journals. One of the meanings given to the word "miscarriage" in America is interruption of pregnancy between the 20th and 28th weeks; abortion then means interruption before the 20th week, and premature birth interruption after the 28th week. As the Toronto workers wrote of abortion, miscarriage, and premature birth, in this order, and did not mention the occurrence of abortion after the 4th and 5th (or 5th and 6th) months, it is evident that they used the words in these senses. Mr. Fisher's argument that "miscarriage" occurs far more frequently before than after the end of the 4th month, and that "any effect on the frequency of miscarriages must have been more magical than nutritional," falls to the ground. Had he taken the trouble to look up the meanings attached to the word in America he would have saved himself from writing several lines of argument based on an invalid premise. It is difficult to understand how he could write that "the frequency of miscarriages in the period of the experiment is surprisingly high, even in the supplemented group," when, as he reports correctly, only 20 lines further on, the incidence, during the period of the experiment, in the supplemented group was 0%.

Mr. Fisher writes that "the work of the People's League of Health has been dealt with ably and forcibly by Doyne Bell in a discussion at the R.S.M." Either Mr. Fisher is wrong in describing the report of this meeting in the *Proceedings* as "full" or Dr. Doyne Bell did nothing of the sort. He criticized one of the conclusions but said nothing about the other—that concerning the effect of diet on the frequency of puerperal toxaemia, of which the authors wrote: "The findings . . . assume a significance which it is hardly possible to over-estimate."

It is hard to believe that Mr. Fisher intended his statement that a demand for the better feeding of pregnant women "is tantamount to an act of sabotage of the first magnitude" to be taken seriously. All the pregnant women in Britain could have double rations for the full nine months of pregnancy without seriously affecting the amount left for the rest of us; while the technical difficulties of allowing special food for this group have already been overcome.—I am, etc.,

Bishops Stortford. JOHN MARRACK.

Help for the Shipwrecked

SIR,—After the sinking of s.s. *Titanic* I carried out experiments with Dr. Argyll Campbell on the preservation of life in rafts and boats after shipwreck, the work being done at the National Institute for Medical Research and at the request of the Board of Trade. The results of the research were published in 1923 in the M.R.C. Spec. Report Series No. 73 on the katathermometer in studies of body heat and efficiency. The results proved that it was essential to keep the body from being over-chilled if rescue could be effected fairly soon. It was shown that a one-piece waterproof dress, designed for us by Sir Robert Davis, offered very great protection from sea-water and wind.

In the appointment of a committee to consider this subject the Medical Research Council seems to have taken no notice of this work. With the aid of Mr. Martin Hill, secretary of the Liverpool Steamship Association, I got in touch with the Ministry of Shipping and Transport two years ago and was able to advise the Ministry to provide a suitable protective dress, and to urge the supply of water above all, and biscuit as the best food, food being of least importance. The Ministry, in place of the one-piece dress of Sir Robert Davis, designed one consisting of overall trousers, a tunic, and a hood, the whole being made of light, yellow oilskin, and packed into the hood to be carried on the back by the sailors just as a gas-mask is carried. Of these dresses 200,000 have been issued, and the highest commendation has been made of their use, not only as a protection from cold but also in the Tropics; the bright yellow colour is seen from the air, and the hood has been found useful for catching rain. Gloves are provided for the tillerman, while others can for warmth withdraw their hands within the sleeves, which have an elastic cuff. The protective dress has "zip" openings in the legs, which allow the legs to be massaged if they become numb.

I have had submitted to me the detailed instructions given to the shipowners for provision of boats; the only new point, I think, stated in the recent report of the M.R.C. Committee is that foods rich in protein, because they increase the need for water, should be avoided. One of the most important provisions made by the Ministry is a lamp carried by each sailor which allows him to be picked up by the boats in the dark. One rescue ship made for what was thought to be a ship on fire and found numbers of sailors floating about with their red lamps glowing, buoyed up as they were by their life-belts.—I am, etc.,

Chalfont St. Peter LEONARD HILL.

Pyogenic Skin Infections and the Skin-carrier Rate

SIR,—My address is, I hope, adequate apology for my delay in replying to Dr. George Discombe's letter (Sept. 26, p. 378). The controls were healthy personnel who had not suffered from impetigo to their knowledge. They were drawn wherever possible from the same units as the patients and were living under the same conditions. The swabs were taken on admission, the patients having had no treatment for the preceding 24 hours. All group A patients were suffering from impetiginous lesions of the face and/or neck. They were not suffering from boils.

In the original more extensive notes from which my article was compiled, I did, in fact, calculate percentages as Dr. Discombe has done. I agree that they appear more striking. In that they could be extracted by anyone interested from the table I gave, I preferred to return all figures as percentages of the whole group, a more direct and, I believe, more just method of presentation. I knew full well that it would be less dramatic.

I have not my original notes with me, and, therefore, must accept Dr. Discombe's statistical corrections of the percentages for the β-haemolytic streptococci. I know Dr. Bradford Hill's book well. I confess at the time of writing the article I was more interested in the distribution of the pathogenic staphylococci. I hope I have answered his questions.—I am, etc.,

NICHOLAS H. MARTIN.

Filaria Worm in the Eye

SIR,—When I was in N.E. India over 40 years ago worm in the eye was very common in horses, and I had quite a collection which I removed myself. It was necessary to immobilize the horse, which was no easy matter but essential if you did not wish for a possible disaster to your operation or yourself, cocainize the eye, then wait, while kneeling on the horse's neck, for the worm to appear in the anterior chamber, and plunge a well-guarded knife slantwise into the anterior chamber. The worms varied in length from 1½ to 2 inches.

The eye was always inflamed and the cornea opaque with a milky fluid before operation, but cleared up in a few days with the application of yellow oxide and atropine ointment. This inflammatory condition was the first warning of eye trouble, the syce remarking that the eye was "sick with running water." The condition frequently destroyed the eye. It was believed that the disease "kumree," then very common among horses, was caused by these worms becoming encysted in the spinal cord, the symptoms being progressive paralysis and dragging of the hind quarters, culminating in complete paralysis.

Later in Nigeria I found filaria very common, and I was myself a sufferer with worm in the eye, which at times caused me some inconvenience. I have frequently seen it wriggling in my eye and under the skin of my temple. The trouble lasted six years and was preceded by a calabar swelling. The worms are also common in antelopes. I have removed some of several inches from the pleurae; the animals never appeared to be out of condition.—I am, etc.,

Bournemouth. E. A. CHARTRES.

Aetiology of Lung Cancer

SIR,—In the leading article "Aetiology of Lung Cancer" in the *Journal* of Feb. 13 (p. 194) there is some criticism of my paper on "Lung Tumours in Mice and Man" (p. 179). I tender the following reply.

After referring to the high incidence of lung cancer in the Schneeberg and St. Joachimsthal miners, attention is drawn in the leading article to the differences between the mouse and human lung tumours. It is stated: "The first and most obvious [difference] is that lung tumours are exceptionally common in some strains of mice; their incidence in control animals in some of these experiments was 20%." I cannot see how this differs from the condition in the above-mentioned miners. Surely, it is a resemblance, not a difference, between the mice and human beings. Further, it is stated that in mice the lung tumour is usually an adenoma in which malignant change is the exception. This was certainly not the case in the experiments with the dusts, where the malignant tumours were more numerous than the simple adenomas.

I have not stated that nodular silicosis gives rise to cancer of the lung. My mice did not develop nodular silicosis of the lung during the dusting with silica, although the incidence of lung tumours was definitely increased and there were silicotic nodules in the tracheo-bronchial lymph nodes of about half the mice. In a previous paper I have suggested that when silicosis of the lung—i.e., the nodular condition—develops it may inhibit cancer development. Further, silicosis itself may be considered a type of multiple tumour, although not malignant, of course. In my experiments with iron oxide dust the resulting tumours were more numerous and more malignant than those produced by silica dust. I consider iron oxide at least as active as silica in the case of mice and man.

At no time did we find the dusting experiments tedious, since we were the first (1932-4) to obtain positive results. This is due to paying proper attention to the time and other factors. Other researches obtained negative results because their experiments were of too short a duration or they used non-susceptible animals as subjects. The main object of our experiments was to obtain clues to prevention or cure of lung cancer —a difficult problem and not easy to approach.—I am, etc.,

London, N.W 3. J. ARGYLL CAMPBELL.

Small-pox in Scotland in 1942

SIR,—At a meeting of the Section of Epidemiology and State Medicine of the Royal Society of Medicine on Jan. 22 I did not state, as reported in the *Journal* of Feb. 13 (p. 199), that encephalitis following vaccination did not occur in infancy, but merely emphasized its rarity during that period, and referred to a paper (*Brit. J. Child. Dis.*, 1930, **27**, 245) by Dr. T. F. McNair Scott, who could find only 41 cases of this kind. It is, therefore, most desirable that vaccination should be performed during the first year of life.—I am, etc.,

Kensington, W 8. J. D. ROLLESTON.

The Measure of Night Vision

SIR,—Mr. N. Bishop Harman (Jan. 9, p. 43) has rightly emphasized the importance of a standard degree of illumination in the estimation of night vision. This need has also been recognized by military ophthalmologists, and all Army night-vision sets are tested by a photometer and the calibration of individual instruments determined in relation to a fixed standard.

Two facts should be differentiated in the investigation of night vision—namely, the rate and degree of adaptation. I am interested to note that Mr. Harman's figures are similar to mine in that there is a deterioration with age, although it is probably more in rate than in degree.

Mr. Harman credits me with the Army test, which I hasten to disclaim. It was devised by Dr. Craik of the Psychological Laboratory, Cambridge, under the auspices of the Medical Research Council, and is in general use throughout the Army. —I am, etc.,

B. W. RYCROFT,
London, W Major, R A M C

Artificial Respiration

SIR,—May I answer some points made by both private and public correspondents? Dr. W. J. Burns Selkirk (Feb. 6, p. 173) writes that when the Schafer operator withdraws his pressure gravity causes the viscera to resume their former position, and that the more toneless the viscera the more vigorous will be their resumption. If he will try Schafer on a dead body he will see how much "vigorous resumption" there is compared with a live and bouncing patient. My article (Dec. 26, p. 751) was based on practice because of the conflicting figures of theorists and of the lack of scientifically controlled work on drowned men. But in theory Eve's method is also far superior. Schafer admits the necessity for raising the hips to allow water to drain out of the upper chest; this is done throughout rocking, not just for a preliminary moment. But rocking scores most during inspiration. Gravity, acting on heavy organs at 45 degrees, pulls down the diaphragm by the visceral ligaments. Is it not likely to be superior to a method which depends on almost non-existent elasticity and on the effects of gravity acting—owing to the displacement of the viscera by manual pressure—through only 5 or 10 degrees? In Schafer the viscera can do no more than roll gently back into their original position; in rocking they slide strongly down towards the pelvis, exerting a powerful diaphragmatic pull and positive inspiration.

I have good reason to believe that statistics of the results of artificial respiration during this war will come as an unpleasant shock. If, as has been said, this is due to faulty technique, Schafer's method must be far from simple, for it is applied at sea by specially trained and practised doctors and first-aid men. If these men cannot apply it properly, why teach only Schafer to quickly trained men when there is such a very simple alternative?

It appears from preliminary work that Eve's method is likely to be superior in its effects on the circulation also. Rocking asphyxiated babies has been the method of choice of many obstetricians for years. Although the baby may be wrapped in blankets and rocked in the arms, it may be better to use a warm old-fashioned rocking cradle. As both circulation and respiration are stimulated without producing shock, it may prove as applicable to "white babies" as it is to blue ones.

Finally, may I beg enthusiasts not to imperil the method again by inventing special apparatus. A stretcher and some support is quite enough. (A possible exception to this may be the fitting of a foolproof clutch to the tilting system of operating tables so that "anaesthetic asphyxias" may be rocked.) For ten years—during three of which hundreds of men have drowned—this life-saving method has been in abeyance because of the impression that apparatus is a necessity.—I am, etc.,

G. H. GIBBENS,
Surgeon Lieutenant, R N V R

Starvation in Europe

SIR,—The public and the medical press within recent months has drawn attention to the gravity of the food situation in the occupied countries of Europe. Leading articles on the subject have appeared in the *British Medical Journal*, in the *Lancet*, and in several newspapers (e.g., *Manchester Guardian* and *Sunday Times*). It is doubtful, however, if the true proportions of the emergency are yet generally realized. From many and authentic sources there is pouring into this country a mass of information which leaves no doubt that in some regions (e.g., Belgium, Greece, and France) a state of virtual famine exists. Much of this information comes from trained neutral observers (Swedish and Swiss) who have in many instances been engaged in Red Cross relief services in the countries concerned. From Greece, for example, there is conclusive evidence that large numbers of the population have been reduced to the state of "living skeletons," that many have died in the streets, and that in some districts of Athens 9 out of every 10 children born have died within six months. In Belgium the position is also grave. Dr. E. J. Bigwood, a distinguished public health worker, whose investigations for the League of Nations are well known, has given striking evidence in a recent memorandum (Dec. 4, 1942). He points out that a major factor in determining the famine situation in Belgium is that, whilst this country in pre-war days derived about 70% of its bread cereals from over-seas, the blockade has shut down this main source of bread and of the cereal feeding stocks for animals. These have had to be slaughtered with a consequent wholesale reduction in meat, milk, cheese, and other dairy produce. Dr. Bigwood has shown that the mortality rate is rising steeply, due mainly to a spread of tuberculosis and to the deaths of infants from infectious diseases, especially bronchopneumonia, and that among the survivors deficiency diseases, such as hunger oedema, scurvy, anaemia, and rickets, are common. Even as early as 1941 in Brussels there was a stunting of growth in 56 to 78% of children of pre-school age and in 51 to 84% of school-age children, whilst for the adolescent the situation is described as tragic. According to the main infant clinics in Brussels the infantile mortality had increased by 300 to 400% even before April, 1941. The condition of mothers is equally grave. During pregnancy women fail to gain their proper increment of weight, and, as the four chief university obstetric clinics in Brussels, Ghent, Liége, and Louvain have shown, by January, 1942, the incidence of premature births had increased by 300%. The incidence of tuberculosis in pregnant women had increased by 100%. The poor nutritional state of the nursing mothers is exemplified by the fact that the mortality was as high in breast-fed as in other infants.

It is apparent that the famine is affecting with tragic emphasis the mothers and children of Belgium and Greece and, as

Dr. Kershner has shown, of France. To these countries some Red Cross relief is being conveyed by Swedish, Swiss, and Turkish agents, but the shortage of materials on the Continent generally imposes a serious restriction on these efforts.

It is for these reasons that the Famine Relief Committee has sought permission from the Allied Governments for "navicerts" to send 2,000 tons of dried milk and vitamins each month to Belgium and Greece in neutral ships to be devoted especially to the succouring of the starving mothers and children. Their estimate is based upon an assessment of the needs of these countries drawn up by an influential committee containing such distinguished authorities as Dr. Harriette Chick and Prof. J. C. Drummond. It is understood that the foodstuffs and ships are available, that the Governments of Belgium and Greece are willing to defray the cost of materials and transport, and that the Red Cross Societies can make the appropriate arrangements with the occupying Power and the other Governments concerned. Recently the Prime Minister of Belgium stated that his Government had decided to ask the Allies for "navicerts" for these moderate quantities of foodstuffs to save the lives of the young people of his country. It is understood that the Famine Relief Committee, whose chairman is the Bishop of Chichester, has the support of the Archbishops of Canterbury and Westminster.

The object of this communication is to draw the attention of the medical profession of this country to the catastrophe which is rapidly overwhelming Europe and to the urgent need for an impartial consideration of measures directed to the relief of those members of the community who always suffer severely in a famine area—namely, the pregnant and nursing women and the children. To realize the measure of the emergency it is only necessary to remember that the area covered by the blockade is many times greater than that which existed during the last war. During that war the situation in Northern Europe, moreover, was ameliorated by the large relief shipments of food (100,000 tons a month) to Belgium under the Hoover Scheme.

This plea for an unprejudiced consideration of a moderate relaxation of the blockade before the tragedy of irretrievable disaster breaks upon Europe is made with a full consciousness of the sanction inherent in the blockade as a potent instrument for speeding the downfall of Nazi tyranny and the time when the starving peoples will be re-fed. It is based upon the conviction shared by the Famine Relief Committee and others who have studied the question closely that a considerable and perhaps critically important amount of relief can be conveyed to Europe and distributed under adequate Red Cross control without endangering the military efficacy of the blockade.

There is conclusive evidence from the neutral Red Cross agents in the occupied countries that the relief food materials already sent are controlled for the benefit of the local populations, and there is implicit in their reports the conviction that the additional shipments which they so earnestly demand would be distributed under equally secure control. This conviction must be shared by the starving peoples themselves. There is the risk that refusal on our part to send relief to the utmost of our power, within the restrictions necessarily imposed by the blockade, will tend to rouse a just indignation in those who are despoiled of aid which their own Governments in this country are anxious to send, and which they are entitled to expect. Further, as the *Manchester Guardian* points out, "to refuse 'navicerts' for this purpose would be to add wantonly to the difficulties of post-war recovery."

—I am, etc.,

JAMES YOUNG,
Professor of Obstetrics, University of London.

London, W.12.

Obituary

W. J. TURRELL, M.D., D.M.R.E.

We regret to record the death recently at the age of 77 of Dr. W. J. Turrell, consulting physician to the department of physical medicine at the Radcliffe Infirmary, Oxford.

Walter John Turrell, the son of the Rev. H. J. Turrell, was born in 1865 and was educated at Turrell's Hall and Exeter College, Oxford. He pursued his medical studies at the London Hospital, and took the M.B., B.Ch. of his university in 1890, proceeding to the M.D. two years later. In 1921 he took the D.M.R.E., Cambridge. After qualifying he was house-surgeon at the Radcliffe. In the war of 1914-18 Dr. Turrell served as a major in the R.A.M.C.(T.), and was in charge of the physiotherapy department of the Third Southern General Hospital at Oxford. Dr. Turrell did much to develop his specialty in this country, and his distinction in this field was recognized by his transatlantic colleagues when in 1933 he was awarded the Golden Key for research in electrotherapy at the American Congress of Physiotherapy. He was president of the Duchenne Society for the Advancement of Physiotherapy, which he founded in 1934, and was at one time president of the Electrotherapeutic Section of the Royal Society of Medicine. At the Annual Meeting of the B.M.A. at Oxford in 1936 Dr. Turrell was president of the Section of Physical Medicine, having previously served as vice-president of the Section of Radiology and Electrology at the Portsmouth Meeting in 1923. He was a member of Council, 1912-13. He contributed an article on electrotherapy to the 13th edition of the *Encyclopaedia Britannica*, and wrote widely on the subject.

We are indebted to Dr. P. BAUWENS for the following appreciation: The sad news of Dr W. J. Turrell's death must have filled the hearts of his friends and colleagues with the deepest sorrow. Some will remember him as a teacher, others as a research worker bent on putting medical electrology on a scientific basis. Yet others will think of him as one whose ingenuity enabled him to put to use such prosaic objects as skewers, primus prickers, funnels, inner tubes, or jam jars, and convert them into effective electromedical apparatus. He will live in the memory of all who knew him as a great man. The furtherance of his branch of medicine was his constant concern. To this end he founded the Duchenne Society for the Advancement of Electrotherapy in 1934. The members of this society will wish to pay the highest tribute to the memory of their late president. A short monograph entitled *John Wesley, Physician and Electrotherapist* he ended with the words: "There are some men whose voices echoing through the past we still seem to hear, and whose past deeds and writings continue to influence the future." Such words could not have been more appropriate had he himself been the object of the monograph.

Dr. F. HOWARD HUMPHRIS writes: The loss that we have sustained by the death of Turrell of Oxford is difficult to assess properly or to appreciate at its true value. He was a great-souled English gentleman, single-minded, with an abiding purpose—that purpose, the aim and object of his life, was the putting of England in the forefront of nations in the use and practice of electrotherapy. That his knowledge of that science qualified him so to do, and made him a leader of it who could have accomplished that object, his writings and his book on the subject afford ample proof. In the U.S.A., a country more enlightened than most in the art and science of electrotherapy, Turrell's greatness was liberally and generously recognized. He was one of the first three European medical men to be awarded the Golden Key for distinguished service to electrotherapy. His place cannot be filled. His loss to medicine in general, and to electrotherapy in particular, is irreparable.

G. W. CRILE, M.D., LL.D.

Prof. GREY TURNER writes: George Crile will always be associated with what is so often spoken about as "surgical" physiology, for in his early days he spent most of his energies trying to find out how the body reacted to disease and especially to the traumatism of surgical intervention. His early work on shock is apt to be forgotten, but his idea of trying to control the peripheral circulation by the wearing of a rubber suit was certainly a notable contribution. His name ought always to be remembered in connexion with the revival of blood transfusion, for in that field he was an early worker and taught us a practical method of making the direct connexion between the arteries of the donor and veins of the recipient. It was Sir Henry Butlin who insisted on the necessity for removing the corresponding lymph nodes when operating for malignant disease of the tongue, but it was Crile who taught us the most convenient way of carrying this out by the plan of operating which is now universally known as "Crile's method." His idea of "stealing the thyroid" was an important feature of the management of the worst cases of hyperthyroidism in his hands. None of those who visited his clinic will ever forget the arrangements that were made for carrying out this plan. Each thyroid patient was nursed in a separate room and the ritual associated with the early stages of general anaesthesia was gone through on several successive days, until finally on the selected morning, which was not known to the patient, anaesthesia was carried to completion and Crile operated in the patient's room. Several of these operations would be carried out on any one day, and Crile fairly ran about from room to room operating in each and with great success. His interest in the suprarenal was greatly stimulated by his experience as a surgeon with the American Army during the last war. It was in furtherance of his interest in the ductless glands that he and Mrs. Crile made a game-hunting expedition to Africa not long before this war with the object of collecting, examining, and carefully weighing the suprarenals and other ductless glands obtained from the animals that fell to his gun, the idea being to correlate these facts with the size and habits of the animals concerned. It was a wonderful evidence of his resilience that when he had to retire from the Lakeside Hospital on attaining the age limit of 65 he at once transferred his energies to the large private institution known the world over as the Cleveland Clinic, where he continued to work almost to the time of his death. Always a good friend to this country, he acted for years as a sort of liaison officer between the surgical profession here and in America, and he never lost an opportunity of keeping those relations warm. He was tremendously elated at his election to the Honorary Fellowship of our own Royal College in 1913 and was most enthusiastic about what he called the delightful ceremony at the time of his admission during the presidency of Sir Rickman Godlee. In his own beautiful home in Cleveland he was the perfect host, and those who had the privilege of staying there must also cherish vivid recollections of those wonderful week-ends spent at his country estate, where he seemed to find such relaxation in the saddle. He had a great gift for friendship, which he followed with as much enthusiasm as the pursuit of his profession, and he will for long be remembered by hosts of surgeons the world over.

We regret to announce the death on Jan. 9 of Dr. **MICHAEL BEHR** of Swindon at the early age of 41. Dr. Behr was born in South Africa and came to this country to complete his medical studies at the Middlesex Hospital, qualifying M.R.C.S., L.R.C.P. in 1926. He was appointed an assistant medical officer to the G.W.R. Medical Fund Society of Swindon in 1927, and for the past 16 years has been one of the most popular members of the staff. He was especially interested in midwifery, and conducted ante-natal clinics for the Borough of Swindon and was on the staff of the maternity hospital, where his services as obstetrician were in great demand. His ability, his courtesy and kindness endeared him to all his patients, and he was held in high esteem by his professional colleagues. He regularly attended meetings of the local Division of the B.M.A. and was a member of its executive committee. His untimely death, following an attack of coronary thrombosis ten months before, has robbed the medical profession and community of Swindon of an outstanding personality, whose services will long be remembered with gratitude and whose place it will be difficult to fill. He adhered faithfully to his Jewish religion and closely followed its observances. Dr. Behr leaves a wife and young son of 13, to whom sympathy will be extended in their tragic loss.—J. L.

We regret to announce the death on Jan. 13 after a long illness of Dr. T. L. **DRAPES** of Chepstow. Born at Enniscorthy, Co. Wexford, in 1877, Thomas Lambert Drapes was educated at Epsom College and Sidney Sussex College, Cambridge, of which he was a scholar. He took his B.A. with first-class honours in the Natural Sciences Tripos of 1900, and then went to St. Mary's Hospital, where he won the Meadows prize in obstetrics in 1903, and qualified M.R.C.S., L.R.C.P. in 1904. He later held the post of house-surgeon, and in 1906 graduated M.B., B.Chir. In the same year he went to Chepstow to join the practice of Dr. Lawrence, eventually succeeding to it on the latter's retirement. He was also medical officer of health to the Chepstow Urban and Rural District Councils. Dr. Drapes was a keen member of the B.M.A., which he joined in 1909, and only resigned when he became ill in 1935. He was chairman of the Monmouthshire Division in 1931-2. He was awarded the M.B.E. for his services during the war of 1914-18. Interested in sports generally, he found his chief relaxation in a day's racing, of which he was very fond. Dr. Drapes was the kindest of men, unsparing of himself in his patients' interests, and possessed of much charm of manner; these, combined with marked professional ability evoked the affection of all his many patients in a very large practice. He was the ideal general practitioner.

The Services

The King has approved the following appointments and awards in recognition of gallant and distinguished services in the Middle East during the period May to Oct., 1942:

K.B.E. (Military Division): Major-Gen. P. S. Tomlinson, C.B., D.S.O., late R.A.M.C.

C.B. (Military Division): Brigadier A. J. Orenstein, C.M.G., C.B.E., South African Forces.

C.B.E. (Military Division): Major-Gen. D. C. Monro, late R.A.M.C.; Brigadier (temp.) E. Phillips, D.S.O., M.C., late R.A.M.C.; Col. H. G. Furnell, D.S.O., Australian Military Forces; and Col. T. D. MacG. Stout, D.S.O., O.B.E., New Zealand Military Forces.

O.B.E. (Military Division): Col. (acting) D. Bluett, R.A.M.C.; Cols. (temp.) N. Cameron, A. T. B. Dickson, and J. Morrison, M.C., R.A.M.C.; Lieut.-Cols. J. Chandra and W. E. R. Dimond, I.M.S.; Majors (temp. Lieut.-Cols.) H. S. Allen, M. R. Burke, G. A. H. Buttle (Reserve of Officers), R. K. Debenham, and C. B. Levick, R.A.M.C.; and Major A. E. Porritt, R.A.M.C.

M.B.E. (Military Division): Capts. (temp. Majors) A. H. R. Champion, J. W. A. Dennis, E. B. Hacking, R. J. Kellar, W. H. Purves, H. L. W. Sixsmith, and B. C. Tate, R.A.M.C.; Capt. (temp. Major) J. Revans, I.M.S.; and Capt. B. De Burca, I.M.S.

M.C.: Capts. (temp. Majors) C. H. George and M. S. Williamson, R.A.M.C.; Capts. B. A. M. Brown and W. Darby, R.A.M.C.; Capt. V. F. Siqueira, I.M.S.; and Capt. S. Kapila, I.M.S. (Reserve of Officers).

CASUALTIES IN THE MEDICAL SERVICES

Prisoners of War.—Capt. J. R. Gibbs, R.A.M.C., Capt. J. H. Gibson, R.A.M.C., Temp. Major J. W. D. Goodall, I.M.S., Capt. J. W. Lillico, I.M.S., Capt. J. F. McGarity, I.M.S., Capt. F. E. McLaughlin, I.M.S., Temp. Major R. Stuppel, R.A.M.C.

Wounded.—Capt. W. K. Badgett, R.A.M.C., Capt. R. W. Davidson, R.A.M.C., War Subs. Capt. R. C. Meek, R.A.M.C., Lieut. D. T. Milnes, R.A.M.C., War Subs Capt. S. D. V. Weller, R.A.M.C.

Missing.—Capt. G. F. Allan, R.A.M.C.

Wounded or Injured.—Prob. Temp. Surg. Lieut. A. E. de la T Mallett, R.N.V.R., Temp. Surg. Lieut. G. R. Walker, R.C.N.V.R.

DEATHS IN THE SERVICES

Lieut.-Col. **DONALD DE COURCY O'GRADY**, D.S.O., R.A.M.C. (ret.), died on Jan. 28. He was born on May 31, 1881, the son of Capt. S. de C. O'Grady, and was educated at the Naval College, Eltham, and at Dublin, where he took the L.R.C.P.&S.I. and the L.M. in 1905. After holding a house post at the Royal City of Dublin Hospital he entered the R.A.M.C. and became a specialist in dermatology while serving in India. During the war of 1914-18 he was mentioned in dispatches and was awarded the D.S.O. and the Croix de Guerre. After his retirement he settled in practice in East London. He leaves a widow.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

The Raymond Horton-Smith Prize for the best M.D. thesis during the academical year 1941–2 has been awarded to E. T. C. Spooner.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

A meeting of the Council of the College was held on Feb. 11, with Sir Alfred Webb-Johnson, President, in the chair. A resolution of condolence was passed on the death of Sir Arbuthnot Lane, past member of the Council. Mr. W. H. Bowen and Mr. P. J. Moir were re-elected members and Mr. N. F. Sinclair, Mr. W. D. Doherty, Col. A. H. Whyte, Surg. Cmdr. J. B. Oldham, Brig. H. C. Edwards, Mr. B. H. Burns, and Surg. Capt. L. C. Rogers were elected members of the Court of Examiners for one year from March 11, 1943. Miss Alice Bloomfield was elected an Examiner in Midwifery under the Examining Board in England for the remainder of the year 1942–3. It was decided to recognize the post of resident surgical officer at the Chelmsford and Essex Hospital for the six months' surgical practice required of candidates for the Final Fellowship Examination. Mr. H. S. Souttar was appointed Bradshaw Lecturer and Mr. J. Johnston Abraham Thomas Vicary Lecturer for 1943. Mr. H. E. Griffiths was appointed a Hunterian Professor for 1943 in place of Mr. W. Bremner Highet. It was reported that new by-laws had been approved giving the College power to make the Primary Fellowship Examination solely postgraduate and to add pathology as an additional subject. Revised regulations will be published at a later date and the new regulations are likely to come into force in 1944. In view of the many inquiries which had been received it was decided to continue the opposition of the College to the extension of the scope of the Mrs. Emily Wilson Barkworth Trust. A letter was received from the Winnipeg Medical Society thanking the Council for a relic of Museum furniture which had been converted for use as a gavel. Dr. J. Newman Morris, F.R.A.C.S., was introduced and conveyed a message of greetings from the Royal Australasian College of Surgeons. In return the President handed to him, as a token of friendship to the sister College, a first edition (1664) of Willis's *Anatomy*, the illustrations of which are by Sir Christopher Wren.

Diplomas of membership were granted to J. M. Titcombe and Mary W. P. Huddart and to the 221 candidates whose names were printed in the report of the meeting of the Royal College of Physicians of London in the *Journal* of Feb. 20 (p. 238), and Diplomas in Public Health were granted to the 9 candidates whose names were printed in the same report.

Medical Notes in Parliament

Beveridge Report: Health Provisions

Sir JOHN ANDERSON, on Feb. 16, speaking on a motion proposed by Mr. Greenwood welcoming the report of Sir William Beveridge on social insurance, said he would deal first with the proposal for a comprehensive medical service. This implied the reorganization of the panel practitioner system of National Health Insurance, existing general and specialized health services of local authorities, the major hospital and institutional services, and so on, and their development into one unified and comprehensive service covering the people as a whole. The Beveridge report viewed this as a service organized not by the proposed Ministry of Social Security but by the Health Departments and designed for positive health and prevention of disease as much as for treatment and cure.

The Government welcomed this conception of a reorganized and comprehensive health service. It was the consummation of a process which had been going on steadily under successive Governments for many years—a constant movement to improve and make more comprehensive the personal health services. Some 18 months ago the Minister of Health had announced the general lines of a plan for reorganizing the hospital services. The Health Departments had given attention to other aspects of the personal medical services, including, particularly, the draft interim proposals of the Medical Planning Commission of the B.M.A. It would be premature to attempt now to formulate details of the new scheme, and the Beveridge report made no such attempt. On all these matters the Health Departments would seek the help of the main organizations—local authority, voluntary, or professional—on whose active participation the success of any reorganization must depend. In consultation with these the shape of a new service would be worked out and then necessary legislation would be prepared.

Main Features

For the moment it would suffice to indicate some of the main features which, in the Government's opinion, must determine the general nature of the reorganization. The object was to secure through a public, organized, and regulated service that every man, woman, and child who wanted it could obtain, easily and readily, the whole range of medical advice and attention through the general practitioner, the consultant, the hospital, and every related branch of professional up-to-date method. The fullest possible use must be made of existing resources, such as the tuberculosis, cancer, and other services of the local authorities. The principle of the new service must be one of co-operation of public authorities, voluntary hospitals, and other voluntary agencies, and of the profession towards one common end. There must be no doctrinaire scrapping of good existing resources, nor must there be overlapping. Responsibility for seeing that in any area the service was full and efficient must be ultimately on one public authority. Experience justified putting this ultimate responsibility in any area on to the local government machinery, working often over larger areas and certainly in consultation and collaboration with voluntary agencies.

Private Practice and the Family Doctor

Professional interests, the well-being and integrity of the medical profession, not only one of the oldest and most honourable, but one on which the success of any scheme would inevitably depend, must be amply and properly safeguarded. The Government recognized that the profession was approaching this major reorganization in the progressive spirit which was expected of it. Most important of all it was necessary to maintain to the greatest possible extent the principles of free choice of doctor and of the family doctor relationship as the background of general medical practice, to create the least possible disturbance of existing association between doctor and patient. In the view of the Government this need not be inconsistent with group public practice and well-equipped clinical centres, a project which underlay most of the current thought on the future of family practice. The Government had no intention of forcing the new services on those who preferred to make private arrangements for medical attendance or hospital treatment. Equally the position of the great voluntary hospitals must be safeguarded.

In general the public health services of this country could already challenge comparison elsewhere. But with the war and the chances of post-war reconstruction there was an opportunity to pull together many loose strands and to build up the whole service until it justified in every sense the word "comprehensive." This opportunity would be quickened by the mass return of young doctors from the Forces. The Government did not intend to let that opportunity be missed. For certain forms of treatment—notably dentistry and ophthalmology and possibly also obstetrics—there was a marked deficiency of personnel, and it must inevitably be many years before this shortage could fully be made good.

Dr. HADEN GUEST asked whether the unified and comprehensive medical services were to be available for all members of the community, irrespective of their income. Sir JOHN ANDERSON said the scheme was comprehensive in two senses: it would cover all forms of treatment and it would extend throughout the community. That was the decision of the Government. Dr. GUEST then asked whether the Government could announce any plan for increasing the number of medical personnel. What was it doing to increase the number of women doctors? Sir JOHN ANDERSON said that matter was under discussion.

Children's Allowances

Continuing, Sir John Anderson said that before the publication of the Beveridge report the Government had concluded that whatever might be decided about children's allowances in cash, the most effective measure was full development of child welfare services, which brought benefits directly to the children. As a matter of current policy some 2,000,000 out of 5,500,000 children in grant-aided schools would be provided with dinner before long. It was the view of the Government that cash allowances to parents, if granted, should not be at a rate which would prove an obstacle to the fullest development of the welfare services, and the Government was ready to consider extending these benefits free of cost as part of its scheme. It saw no difficulty in providing services equivalent in money value to 2s. 6d. a head, or even more, per week, as against the 1s. assumed by Sir William Beveridge. For that and for other reasons the proposal of the Government was that the rate of children's allowances should be fixed at 5s. for the second and other children instead of the 8s. recommended in the Beveridge report.

Approved Societies

On what he termed the controversial question of the approved societies, Sir John said that under the existing system of health insurance the sickness risk was separated from other insurance risks with which it would be associated under the Beveridge plan, and there was a voluntary segregation of risk on a large scale within the field of sickness insurance itself. The question now was whether the continuance of approved societies as independent financial units was compatible with a unified system of social insurance under which uniform contributions provided for uniform rates of benefit. Inasmuch as the approved society system was one of unequal benefits for equal contributions, there could be only one answer to that question. It was no light matter to discard institutions which had become part of the social system, and if any method could be devised whereby the societies could continue as agents in administration of the national scheme the Government would gladly consider it. The Departments were considering alternative suggestions.

The Government agreed that what was called in the report a funeral grant, but which it preferred to call a death grant, should be a benefit under the unified system of social insurance. The amount of the benefit required further consideration. Sir John concluded by pointing out that there could be at present no binding commitment. Subject to that, the Government adopted the scheme in principle, and no reservations which he had made would affect the speed and vigour of its preparations. The Government would press forward the preparation of a Bill or group of Bills. When this work had been completed it would review its policy, and Parliament would have an opportunity of pronouncing on the scheme as a whole in relation to other schemes and in the light of the financial situation as it could be estimated at that time.

"A Revolution in Medical Ideas"

When the debate was resumed on Feb. 17 several members criticized the statement of Sir John Anderson on the ground that it should have indicated a Government decision to take immediate steps to carry out the recommendations of the report. Sir **Kingsley Wood** reaffirmed the declaration of Sir John that immediate pledges could not be given. He said the setting up at this moment of a Ministry of Social Security would retard the preparation of schemes arising out of the report. Responsibility for the comprehensive medical service must lie with the Minister of Health, and if they tried to interpose a new Minister they would only hamper and hinder the machine. In the future they might find a place for a Minister of Social Security, but his duty would not be matters like a comprehensive medical service, but rather such matters as the collection of contributions and things of that kind.

With regard to the comprehensive medical service, Mr. Brown and Mr. Johnston would immediately begin negotiations with the medical profession on the lines set forth in the Beveridge report. As one who went through the negotiations in 1911, Sir Kingsley said the task of these two Ministers was considerable. If, as they all hoped, they could bring about the changes which had been outlined already it would mean considerable adjustment as regards general medical practice and all that went with it. Almost a complete revolution in medical ideas and prospects was outlined. In 1911 great hopes were pinned upon the panel system. He did not think many people would pin so many hopes upon it to-day. They would like to see that comprehensive range of services which had been forecast by Sir William Beveridge and many others. These negotiations by the two Ministers and the setting up of this new system would take a considerable time. When dealing with a great and honourable profession such as the medical profession matters had to be settled with the utmost amount of good will on both sides.

Voluntary Hospitals

On Feb. 18 Mr. **Herbert Morrison** wound up the debate. He said the Government accepted the six fundamental principles of the Beveridge report save for the subsistence basis. It accepted the assumption in the report of a comprehensive health service and children's allowances. The health service was on the basis of universality, free benefit, no means test, medical reorganization, and so on.

Dr. **Morgan**: And popular control of hospitals? Does the Government accept representative control of hospitals?

Mr. **Morrison** replied that he had had a good deal of relationship with voluntary hospitals and had started on the principle that he rather wished them to be taken over. But this was a country in which there would always be voluntary effort, voluntary social service, voluntary public service. If that died in this country British democracy would be dead. That was not to say that voluntary hospitals ought necessarily to be preserved. He nearly had the offer to take them over in London but found they were doing good work, and that to take them over would cost the ratepayers a 1s. 6d. county rate. He had said the transfer could be postponed. Was a voluntary hospital necessarily wrong? There were voluntary hospitals in mining communities to which the miners often attached the utmost value. The Government thought it right to intimate that it did not propose to destroy the institution of voluntary hospitals. If it had declared that it would destroy them controversy would certainly develop. The Government had committed itself, subject to certain reservations, to a very big change—a comprehensive public health service. It was working hard to get to the next stage. Mr. Johnston was meeting his Medical Advisory Committee for Scotland to discuss the report with them. Mr. Ernest Brown was likewise going ahead straightway with his negotiations. Other discussions would also go on and not only with doctors. Local authorities, voluntary hospitals, and all sorts of people, including the trade unions, would rightly wish to be consulted.

By 335 votes to 119 the House rejected the Labour Party's amendment expressing dissatisfaction with the declared policy of the Government toward the report and calling for early implementing of the Beveridge plan. It then adopted Mr. Greenwood's motion welcoming the report as a valuable aid on which developments and legislation should be pursued.

Regional Organization of Health Services

Speaking before Mr. Herbert Morrison in the debate on Feb. 18, Mr. **Storey** said he feared there had been a tendency to treat as a matter which could be shelved the creation of a health and rehabilitation service. This could not be shelved. The preparatory work done by the Ministry of Health, the Nuffield Provincial Hospitals Trust, the Rushcliffe Committee on Nurses' Salaries, and the Tomlinson Committee on Rehabilitation must be intensified so that a start could be made with a real health and rehabilitation service. They must take every step to reduce the number of claims for illness and the length of the claims. He disagreed with Sir John Anderson's statement that it was intended to put the ultimate responsibility for the health services on the local authorities. He admired their administration and their hospitals, but co-operation between public authorities, voluntary hospitals, voluntary agencies, and the medical profession would not be easily attained if one of the partners in the co-operation had overriding powers. To place responsibility upon local authorities would require complete reorganization of local authority areas. A health service must be based on an area not conterminous with any present local government area. It must be centred upon a key general hospital, often a teaching hospital, where there were available research, consultative, specialist, and technical facilities, and from which the service would radiate out through other general, lesser hospitals and health centres to the general practitioner and his patient. Already, under the auspices of the Nuffield Provincial Hospitals Trust, local authorities and voluntary hospitals had formed in many areas regional councils, which co-ordinated hospital policy and took action on common problems without interfering with the day-to-day administration or the individuality of the constituent hospitals. By some extension of that system, by widening the representations on these councils, by granting them some authority, Parliament could contrive a more flexible administration of the health services than by placing the whole responsibility on the local authorities.

Pasteurization Processes—Vitamins in Milk

In a series of replies on Feb. 11 to Mr. Purbrick, Mr. **Ernest Brown** said two processes of pasteurization were prescribed in the Milk (Special Designations) Regulations, 1936–42: a "holder" process whereby the milk must be retained at a temperature of not less than 145° F. and not more than 150° F. for at least 30 minutes and be immediately cooled to a temperature of not more than 55° F.; and a high-temperature short-time process whereby the milk must be retained at a temperature of not less than 162° F. for at least 15 seconds and be immediately cooled to a temperature of not more than 55° F. New proposals in connexion with the control of heat treatment were under consideration. He was advised that the temperature and periods of application necessary to destroy tubercle bacilli ranged from about 135° F. for 40 minutes to boiling point for a fraction of a second. He was satisfied that tuberculosis in cows was infectious through the milk to human beings. Mr. Brown added that pasteurization caused no loss of vitamins A and D; the amount of vitamin B_1 destroyed was too small to be detected by the usual methods of analysis. The loss of vitamin C, which was present in milk only in small quantities, was negligible, and was no greater than would result in raw milk exposed to sunshine for a few minutes before delivery. The effect on vitamin E, which was also present only in small quantities, was not known.

Venereal Diseases: Cost of Propaganda Campaign

Mr. **Brown** on Feb. 11 told Dr. Summerskill that the receipts of the Central Council for Health Education for education in the prevention of venereal disease in the current financial year by way of grants from the Exchequer and from local authorities were estimated at £19,000, made up of Exchequer grants not exceeding £5,000 and £6,000 for general and venereal disease work respectively, and local authorities' grants of about £1,000 and £7,000 respectively. The Central Council's function was to provide facilities for the use of local authorities and other local bodies. Its grant income of £13,000 for venereal disease educational work represented working capital for local efforts in support of the Ministry's central propaganda. It was only part of the total expenditure from public funds on education in the prevention of venereal disease.

Treatment of Syphilis in the Army

Mr. **Arthur Henderson** in a reply on Feb. 10 said the drugs used in the Army for the treatment of syphilis were neoarsphenamine, bismuth, and in some cases mapharside. Instructions about the use of these drugs were contained in the specific and general instructions issued to medical officers employed in the treatment of venereal diseases. The Army medical authorities received suggestions from time to time for improvements in this treatment and these were carefully considered.

X-ray Apparatus.—Mr. **Peat** is aware of the shortage of therapy and diagnostic tubes for *x*-ray apparatus. Steps have been taken both in this country and in the United States to remedy the position so far as the exigencies of the war will permit.

Medical News

"Calcium Metabolism and some Present-day Problems in Nutrition." will be the subject of a paper by Dr. J. D. Robertson of the Courtauld Institute of Biochemistry, to be read at a meeting of the Royal Society of Arts, John Adam Street, Adelphi, London, W.C.2, on Wednesday, March 3, at 1.45 p.m. Lord Horder will preside. A sandwich lunch, which should be ordered in advance, can be procured between 1 and 1.30 at 1s. 6d. per head.

A meeting of the Wireless Section of the Institution of Electrical Engineers will be held at Savoy Place, Victoria Embankment, W.C., on Wednesday, March 3, at 5.30 p.m., when a paper by Mr. G. Parr and Mr. W. Grey Walter on "The Amplifying and Recording Technique in Electrobiology, with Special Reference to the Electrical Activity of the Human Brain" will be read and discussed.

The seventh annual medical conference of the Ex-Services Welfare Society will be held at the Waldorf Hotel, Aldwych, W.C., on Thursday, March 11, at 10.30 a.m., when there will be a discussion on "War and the Neurotic and Psychotic." The proceedings will be opened by Lord Horder.

On account of the sudden indisposition of Dr. A. H. Harkness, who had arranged to address the Medical Society for the Study of Venereal Diseases on "Drug Resistance in Gonorrhoea," the meeting arranged for Feb. 27 has been postponed to some future date.

Medicated (lethane) hair oil for the eradication of head lice is being added to the *National War Formulary.* It consists of equal parts of lethane 384 special and a white oil of high boiling-point. Only one application is necessary, especially if the hair is not washed for one week afterwards, but the instructions must be carefully followed. The oil does not cause any undesirable secondary effects. A uniform pack with instructions for use will shortly be available at all chemists' shops. In future the vitamin content of caps. liq. vitamin A et D conc. (*National War Formulary*) will be reduced; each 3-minim capsule will contain 4,500 units of vitamin A and 450 units of vitamin D.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* the notifications of measles showed the largest increase—2,762—in any week since the beginning of 1941. The figure for dysentery was only half that of the preceding week; scarlet fever was down by 153, and whooping-cough by 95 cases; the incidence of diphtheria went up by 88.

The fall in the notifications of scarlet fever and of whooping-cough was fairly general, the only big change from the totals of the previous week being a drop of 54 for whooping-cough in Lancashire. The incidence of diphtheria showed a small general rise in the North; there was no change in the trend of this disease in the South.

During the past month the incidence of measles has been steadily mounting in the South but dropping slightly in the North. As a result there has been an appreciable change in the proportionate distribution: during the week ending Jan. 9 the North Midlands, North-Western, Yorkshire, and Northern divisions accounted for 65% of the total notifications, but during the week reviewed these divisions had only 49% of the total. The largest rises during this week were: Yorks West Riding 348, Glamorganshire 280, Gloucestershire 267, Essex 216, Middlesex 215, Durham 200, Staffordshire 166, London 112.

Dysentery was down by 89 cases, but in Cheshire there was an outbreak of 9 cases, and in Northumberland they went up from 3 to 9.

Five more cases of paratyphoid fever were reported from the outbreak in Sussex, Hastings C.B., which began last week with 27 cases.

In *Scotland* primary pneumonia went up from 363 to 466 notifications: 247 cases, an increase of 61, were reported from Glasgow. The small weekly rise in the incidence of cerebrospinal fever that has occurred this year has been due mainly to the experience of Glasgow, where 21 out of 32 cases were recorded during the week reviewed.

In *Eire* diphtheria notifications rose from 95 to 126. The principal centres of infection were the cities of Dublin 46 cases, and Cork 17.

Returns for the Week Ending February 13

The notifications of infectious diseases during the week in England and Wales included: scarlet fever 2,073, whooping-cough 1,596, diphtheria 895, measles 17,308, acute pneumonia 1,542, cerebrospinal fever 124, dysentery 85, paratyphoid fever 4, typhoid fever 1. In the great towns 131 deaths were attributed to influenza.

No. 5

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Feb. 6.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1943					1942 (Corresponding Week)

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes paratyphoid A and B for Northern Ireland.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to The EDITOR, British Medical Journal, B.M.A. House, Tavistock Square, London, W.C.1.

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

Telephone No.—B.M.A. and *B.M.J.*: EUSTON 2111.

Telegraphic Addresses.—EDITOR, *Aitiology Westcent, London;* SECRETARY, *Medisecra Westcent, London.*

B.M.A. Scottish Office: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Cheiropompholyx

Q.—*Is it accepted that cheiropompholyx is caused by a fungous infection in distant parts of the body?*

A.—The term "cheiropompholyx" is more significant if reserved for an eczematous eruption of itching, deep, tense vesicles which erupt, periodically or episodically, without obvious cause, although nervous factors and local irritation are provocative, as in other types of eczema. If cheiropompholyx extends to the forearms the eruptions there are frankly eczematous, and not infrequently cheiropompholyx develops as part of an extending eczema. Relapses are common. A similar vesicular eruption occurs on the hands in some cases of epidermophytosis of the feet and should be called an epidermophytid. This is an allergic reaction to the epidermophytoxin, and it clears up when the foot infection has been eradicated and does not relapse unless reinfection is established.

Treatment of Parkinsonism

Q.—*A married woman aged 54 has suffered from muscular rheumatism all her life. Nine years ago she noticed weakness and dragging of her right leg, and inability to raise the arms above the head following a "chill." During the past three years she has developed the symptoms of Parkinsonism: shuffling gait, mask-like expression, and rigidity of limbs. She had a special examination five years ago, when nothing abnormal was found. Examination to-day shows generalized muscular tenderness and rigidity. She complains much of pain in the back of the neck on exposure to cold, reflexes and disks normal, and nothing unusual found in cardiovascular system. Would radiant heat, massage, passive movements, or any other treatment be of value in this case? The symptoms are temporarily relieved by stramonium.*

A.—In the first place, there is no cure for Parkinsonism, but some of the symptoms can be alleviated by suitable means. Massage or electrotherapy is of no help; but passive movements to straighten the limb, and particularly the trunk, often help to overcome the discomfort of the bent attitude. Because of the muscular rigidity there is apt to be pain in the region of certain joints, particularly the neck and the shoulders, and free passive movements should be carried out twice daily to prevent the onset of pain or to relieve it if it is present. The muscular rigidity itself can usually be diminished by drugs of the hyoscine, stramonium, or belladonna group. A useful way to prescribe stramonium is in the form of the tincture, beginning with a dose of 15 minims in water thrice daily after meals, the dose to be increased by 5 minims weekly until the patient complains of dry mouth or misty vision. Then a dose just short of that should be continued with. Very occasionally stramonium, like hyoscine, may give rise to mental confusion in submaximal doses, and if so the drug should be stopped. In certain cases hyoscine acts better than stramonium and should be given as tab. hyoscine hydrobromide gr. 1/150 under the tongue, thrice daily

Treatment of Paratyphoid Carrier

Q.—*A young woman who had an acute attack of paratyphoid over 5 months ago is still a carrier. After many and varied medical treatments the faeces are persistently infective. What can be done to clear this up?*

A.—Convalescent patients who have been carrying typhoid or paratyphoid bacilli for five months are likely to become permanent carriers. There is no known method of curing them medically. It is worth while, however, trying the effect of iodophthalein and of succinyl sulphathiazole. Soluble iodophthalein should be given orally in a dose of 4 g. three times a week for thirteen weeks. The patient should be kept on a low-fat diet to avoid unnecessary contractions of the gall-bladder, and the dye should be given in the early morning so that the maximum concentration in the bile is reached at night, when rest and absence of food should help to keep the gall-bladder quiet. Succinyl sulphathiazole should be given in a dose of 0.25 g. per kilo body weight in four daily divided doses for five to fourteen days. If neither of these drugs succeeds in freeing the patient from infection with paratyphoid bacilli, excision of the gall-bladder should be considered. This should not generally be undertaken until the patient has been carrying for at least a year. It is wise, also, to make certain, so far as possible, that the organisms are present in the bile. Cholecystectomy usually cures about 75% of chronic biliary typhoid carriers.

Bacteriology of Diarrhoea

Q.—*Has any work been done on the bacteriology of the recent epidemic of diarrhoea? Is there any reason to believe that it was caused by a virus?*

A.—Sonne dysentery has as usual been widely prevalent recently. There have also been cases of enteritis, mild in adults but severe in infants, in which examination of the faeces has failed to show any of the recognized bacterial causes of such a condition. In these circumstances its cause can only be the subject of speculation. There is no evidence that a virus is concerned, but so far as we are aware no experiments which would test this hypothesis have been undertaken.

INCOME TAX

Travelling Expenses, Residence Abroad, etc.

P.'s inquiries may be sufficiently clear from the following replies.

⁂ (A) Where a single appointment involves attendance at more than one place, any expense "wholly, exclusively, and necessarily" incurred in travelling between them is allowable.

(B) The basis of assessment of the income from an appointment is normally the amount of the previous year. But as the appointment held by P. ceased at Dec. 31, 1941, the assessment based on the previous year's earnings is adjustable to the actual earnings of the nine months ending on that date.

(C) Whether the result of P.'s professional activities when abroad in 1942, whether profitable or the reverse, came within the income-tax field is a matter of some difficulty, and would depend for decision on all the circumstances of his case. In so far as judicial authority goes (Davies *v.* Braithwaite, decided in 1933), the answer is probably in the affirmative.

(D) The fact that P.'s wife has not received a notice of assessment would not invalidate the deduction of tax from her salary. If she is unable to obtain a reply from the inspector of taxes to whom she sent a declaration of income, we suggest that a complaint should be sent to the Board of Inland Revenue, Somerset House, London, W.C.2.

War Damage Contribution

L. inquires whether it is correct that premiums payable for war risk insurance of professional equipment cannot be regarded as deductible for income-tax purposes.

⁂ Yes. The point is explicitly covered by statutory provision and is beyond dispute. The *raison d'être* may perhaps be said to lie in the fact that it is contemplated that the Exchequer may have to contribute directly from the national funds, and therefore bars the indirect contribution resulting from the loss of income tax which would follow from admitting the deduction of premium.

LETTERS, NOTES, ETC.

Pasteurization of Milk

Dr. H. G. Williams (Chalfont St. Peter) writes: In my letter (Jan. 23, p. 112) the figures I gave for the bacteria per millilitre of T.T. milk and pasteurized milk are for Scotland. In England and Wales there is no bacterial count done for T.T. milk, but the methylene-blue test must be passed. The bacterial count for "T.T. pasteurized" milk must not be 30,000 per millilitre and for "pasteurized" milk 100,000 per millilitre. The cooling temperature should be 55° F. and not 50° F. I apologize for this omission and mistake.

A Disclaimer

Dr. D. B. Craig (Redhill County Hospital, Edgware) writes: I wish to disclaim any knowledge of a notice in the *Hendon and Finchley Times* dated Feb. 12, which mentions my name in connexion with work at this hospital. This was entirely without my authority or knowledge.

Correction

In the report of an investigation into the standard of milk supplied to children in the *Journal* of Jan. 30 (p. 140) the footnote marked by an asterisk under the first table should read: "Double the number of cases of meningitis in 1941 as compared with 1938."

BRITISH MEDICAL JOURNAL

LONDON SATURDAY MARCH 6 1943

THE PROBABLE INFLUENCE OF HEALTH EDUCATION ON THE IMPROVING APPENDICITIS MORTALITY RATE

BY

D. B. ARMSTRONG, M.D., Sc.D.

Third Vice-President, Metropolitan Life Insurance Company, New York

These observations are based mainly on experience with the approximately 17 million industrial policy-holders of the Metropolitan Life Insurance Company in the United States and Canada—men, women, and children mostly in the wage-earning sections of the population. They are sufficiently representative, in number and geographically, of the populations of the two countries to be indicative of general conditions. Frequent mortality, morbidity, and other comparisons have confirmed this statement.

Among these millions of policy-holders the performance of appendicitis has been of an arresting and definitive character during the last 30 years or so. After a steady rise in the death rate since 1911, levelling off about a decade ago, the fatality rate started a fairly marked, consistent, and recently accelerated decline. This decline occurred despite a reported increase in the incidence of the disease. We are, in fact, concerned in this analysis with appendicitis as a cause of fatalities and with influences that seem to have affected the prevalence of serious and fatal complications. We are not aware of any new approaches affecting the incidence of the initial disease itself.

The Improvement in the Mortality Rate

That there has been a marked improvement in the death rate from appendicitis is evidenced by the records of industrial policy-holders as well as by those for the general population. There were indications that a maximum level in the mortality rate had been reached during the period 1929 to 1932. Since 1933 the decline has been consistent, and should probably be considered in two phases—1933 to 1939, and 1940 to date. It is believed that the decline in the first of these periods reflects in substantial part certain health educational activities undertaken with increasing intensity during those years. Since 1940, however, while the educational work has continued, subsequent therapeutic interventions have apparently produced an even more pronounced mortality improvement.

We are primarily concerned in these analyses with the first period mentioned above, when for the industrial-policy-holder group the appendicitis mortality rate decreased from 13.2 per 100,000 in 1933 to 10.3 in 1939—a reduction of approximately 22%. If in this group we go back to an earlier peak year (1929), when the rate was 14, the decline by 1939 is 26.4%. It may be safely said that during this period the picture has been influenced by no great new medical discoveries, such as toxoid in diphtheria or other striking immunization or therapeutic procedures, although there may have been some modest advances in surgical skill, some stimulus to hospitalization through voluntary prepayment insurance plans, and other minor influences. Yet the chief variables in the picture seem to be the mortality rate and the cumulative health educational effort to be subsequently described.

Can Health Education be Measured?

It must of course be admitted that one can never "isolate" health education or any other single factor in such a complex picture and give it a specific value. Conditions and results are influenced by other tangible as well as intangible factors, such as the prevailing medical opinion, hospitalization facilities and practices, nursing influences (such as the nursing service which the Metropolitan Life Insurance Company provides for its industrial policy-holders who are under medical care and acutely ill in their homes). Yet one may say that, of all the influences at work upon appendicitis in this instance, health education stands out as an essentially new ingredient. This health education factor seemingly influences not only Metropolitan experience but, as implied above, that of the general population as well. For instance, a drop of over 29% in appendicitis mortality in the Metropolitan experience in 1933 to 1940 is equalled by an improvement to the same degree for the general population in this period.

Health Education plus Sulphanilamide

In passing we should also make a brief reference to the second period—1940 to the present time. This period, as stated, has shown an acceleration in mortality improvement, and there is little doubt as to the reason. The health educational work has been continued and intensified, especially during 1940, but the new factor is the introduction of the sulphonamide drugs, and particularly the use of sulphanilamide intraperitoneally in cases of appendicitis with perforation and peritonitis. In fact, taking the period from 1933 to the first half of 1942, the insured group showed a mortality rate decline from 13.2 to 5.5, or 58% (general population figures are not yet available beyond 1940). The influence of chemotherapy on the last two or three years' experience is brought out by recent hospital reports dealing with deaths from peritonitis following appendicitis. Actually the number of deaths from appendicitis itself has always been relatively small. Perforation and peritonitis are the principal fatal factors. It has been estimated that more than 80% of the deaths from appendicitis are caused by this complication. It is also true that the peritonitis death rate and the incidence of the complication itself have been improving for some time, apparently reflecting the educational efforts during the earlier years. Hospital studies in Philadelphia, for instance, showed a decline in perforated appendicitis from 43% in 1928-9 to 19% in 1937. Now, current reports on acute appendicitis with perforation in certain New York City hospitals show very striking contrasts. One of these reports refers to 742 cases in 1935 to 1939, with about 3% fatal. In 1940 and 1941 this study covered 400 cases, with the use for the first time of sulphanilamide given intraperitoneally where the appendix had ruptured, with *no deaths*. Another series indicates 741 cases of appendicitis with perforation and peritonitis, with 2.7% fatal before the use of the drug. Since beginning the intraperitoneal injection of sulphanilamide these observers record 642 cases with *no deaths.*

Savings in Death Claims

From the point of view of the insurance company, we are interested not only in deaths but also in death claims. The Metropolitan Life Insurance Company in its total death claim experience shows a decline in death claims from appendicitis from $3,032,000 in 1933 to $2,000,000 in 1941, in spite of a marked growth in the size of the company and the amount of insurance in force during that period. In fact, the Metropolitan insurance in force in 1933 was $18,802,984,818, as compared with $25,433,226,148 for 1942. While it is difficult to appraise the cost of health educational and special therapeutic efforts, it can undoubtedly be said that this improvement in death claims represents a saving in one year alone of many times the cost of all the educational activities carried on throughout the whole period in question.

The Health Educational Approach

What specifically were the health educational approaches to the problem? It may be said that a number of agencies have participated in the activity in a rather isolated way. The Health Council in one city, a medical society in another, have taken an interest in the appendicitis problem from the educational angle. However, there has been in the United States and Canada no national sponsorship for this movement, such as one sees for tuberculosis, venereal diseases, cancer, poliomyelitis, etc. The official public health authorities have not been active until recently, though about a year ago the United States Public Health Service published its first bulletin for popular distribution among industrial workers on the subject of appendicitis.

Co-operation of the Medical Profession

The Metropolitan Life Insurance Company was the first nation-wide agency to take a major interest in this problem, and presumably some of the details in the approach made will be of interest. At the start it may be said that an attempt was made to present a simple message, briefly and clearly, to the lay reader. The burden of this was that in case of persistent severe abdominal pain *the doctor should be called* and *no laxatives or cathartics* taken in the meantime. Contrasting experience was presented as to mortality, among those taking cathartics and not taking cathartics, among those receiving *hospital attention early* and hospital attention late. Every effort was made educationally to join hands with the medical profession in stressing the avoidance of self-diagnosis and treatment. One of the leaflets used in the campaign may be quoted in this regard as follows:

> "Appendicitis is one of the leading causes of death among children, adolescents, and young adults, thus taking life during the most productive years. *Self-treatment is responsible for a large number of the 16,000 to 18,000 deaths which occur yearly in the United States through appendicitis.* If a doctor is called promptly and skilled surgical attention obtained when necessary, nearly all such deaths can be prevented."

Aid of the Insurance Agents

Numerous methods and devices were used to arrest the attention of the policy-holder and to give him simple advice in concentrated, dogmatic, and emphatic form. The insurance company, as in its past efforts, made special use of its own field staff of more than 20,000 men—agents who enter thousands of industrial homes periodically, many of them weekly, for premium collection and other business purposes. These men have had a long training not only as insurance agents but also as health educators, and co-operated admirably in the appendicitis educational effort. As a matter of fact, in 1940 alone 93% of the men were active and took an aggressive part during that year. Many of them of course have had personal experience with appendicitis in their own families. Properly equipped with educational material, they serve admirably as health advisers for the families with whom they are in contact. Indeed, the company has hundreds of letters from parents, teachers, physicians, and others expressing gratitude for the part played by Metropolitan literature or the Metropolitan field representative in protecting or saving a life from the hazards of appendicitis. For instance, a New Jersey physician wrote the company the following letter:

> "I wish to call your attention to the admirable attitude of one of your agents in regard to a boy who was stricken with a severe case of acute gangrenous appendicitis. Your agent, who happened to walk into the boy's home, immediately became aware of this situation and, due to his efforts, saw to it that he did not waste any time, communicated with me, and had the boy at Christ Hospital, Jersey City, in a very short time. The agent about whom I write is entirely unknown to me, but, whoever he is, I feel that he played an important part in this affair and deserves an endless amount of praise."

Another report from a Pacific Coast agent is typical of much field experience in this effort:

> "The mother was about to administer a laxative. I opened one of our appendicitis pamphlets and showed it to her, and she immediately called a doctor. A blood count was taken and the baby was found to have appendicitis."

One of the company's assistant managers from a Middle West district wrote in as follows:

> "While I was out with Agent —— I came into a home and found that the baby was sick with a stomach-ache. The mother was about to administer a laxative. I opened one of our appendicitis pamphlets and showed it to her, and she immediately called a doctor. A blood count was taken and the diagnosis of appendicitis made. This certainly was a wonderful help to her, and she appreciated it very much."

Messages Brief and to the Point

During the last concentrated effort with educational literature the agents were equipped with a simple leaflet, which consisted of four pages of text in colour and large type, and with a summary phrased and set as follows:

APPENDICITIS!!
NEVER BELITTLE THESE SYMPTOMS:
Pain or tenderness anywhere in the abdomen
Fever and nausea

. . .

IF SUCH SYMPTOMS PERSIST:
Do not take a laxative
Do not resort to massage or exercise to "work off" the pain
Do not take enemas
Do not take food or drinks

. . .

JUST BE SURE TO DO THESE
COMMON-SENSE THINGS:
Call your doctor without delay
Remain quiet and apply an ice-bag at the site of the pain

In addition to other educational materials the company's leaflets are also liberally provided for distribution by health and educational agencies with a recognized programme in this field. In fact, 1,200,000 copies of one of the company's appendicitis leaflets were distributed in one year, and since the beginning of the organized educational campaign a total of 6,400,000 pieces of educational literature on appendicitis have been placed in American homes. At the same time this campaign was carried out also by nurses employed by or representing the company, who make 3 million visits a year to insured families to furnish bedside care and to teach personal and community hygiene. Nurses and agents of the company were urged to discuss this programme with physicians and other professional and community leaders in their districts. They were asked to study the literature themselves so as to be able to interpret it clearly. The agents were asked to leave copies in at least 50 homes in their areas.

Use of Commercial Advertising Space

The company has also utilized space in its national magazine welfare advertising series—space that monthly reaches approximately 27,000,000 readers, which naturally include all types of policy-holders, as well as a certain percentage of those in the industrial group. This appendicitis advertisement has been repeated since its first presentation, and reprints of it have been made available for distribution by co-operating organizations or individuals, especially physicians, medical societies, and nursing and public health agencies. The text of a recent appendicitis advertisement, under an illustration presenting a physician and mother at the bedside of a small boy, may be quoted in part as follows:

> "HOW INNOCENT IS A 'STOMACH-ACHE'?
>
> A 'Stomach-ache' means *something's* wrong.
>
> True, it may be nothing dangerous But, because it *can* be very serious, no one should treat such a warning signal lightly. . . .
>
> *1. Call a doctor.*
>
> *2. Apply an ice-bag and remain quiet.*
>
> *3. Do NOT take a laxative, food, or medicine.*
>
> The importance of prompt medical attention is clearly indicated in a recent survey of appendicitis cases made by medical authorities. It reveals that the death toll, among those who delayed going to hospital from two to three days, was from *three to four times greater* than among patients admitted to a hospital within the first 24 hours. The survey further shows that fatalities among those who had taken a laxative after pain developed were more than *three times greater* than among those who had taken none. . . .
>
> When in any doubt whatsoever about abdominal pain, call your physician for *safe* guidance—and call him in *time*. Then if serious disease is indicated an early diagnosis and treatment may speed recovery, reduce the cost of illness, and decrease the possibility of dangerous complications.
>
> Send for Metropolitan's helpful free booklet, 'Appendicitis.'"

The effect of such an advertisement on the casual reader is indicated by a copy of a letter in the company's possession, written by a Canadian traveller to the Pullman Company, which reads as follows:

> "About three weeks ago I was travelling on one of your crack trains, and was stricken with a severe stomach-ache. The porter in one of your Pullman cars was most accommodating, and I asked him for, and he was glad to provide me with, some bicarbonate of soda in an endeavour to relieve my pain. He, however, brought me from the club car a bottle of a well-known cathartic, and told me that the conductor in charge suggested that I take a dose of the same.
>
> Very fortunately, I had a recent institutional ad. of the Metropolitan Life Insurance Company that was running in the leading magazines. This ad. was headed, 'How innocent is a stomach-ache?' and advised that you do three things: '(1) call a doctor; (2) apply an ice-bag and remain quiet; (3) do not take a laxative, food, or medicine.'
>
> Now I do believe that if I had not read this advertisement (I am not a medical men, and unfortunately have not been interested too much in physiology) I would have taken this strong cathartic and have had a ruptured appendix.
>
> I decided to get off the train at 4.45 a.m. instead of going through to my destination. I was operated on around 6 a.m., and the surgeon told me that if I had taken the cathartic I would have had quite a gamble with my life."

The Druggists Step In

Posters have also been used—notably a poster for display in drug stores, with the co-operation of the druggists and pharmacists. The national organization representing the drug and pharmaceutical business was perhaps the second major national agency to participate in this effort in a consistent way. The public spirit and leadership of the druggists have met with wide and merited acclaim. The drug-store poster referred to carries an illustration of a man in some distress at the prescription counter evidently seeking medical aid, with the druggist indicating doubt and saying:

> *"It might be appendicitis—*
>
> You should see your doctor.
>
> 16,000 to 18,000 people in the United States die yearly from appendicitis. Many of these deaths could be prevented if the doctor were called at once.
>
> *Self-treatment for abdominal pain is dangerous!*
>
> Do not take a laxative, food, or medicine.
>
> Remain quiet and call your doctor."

This organized effort to combat self-medication has been strengthened through other lines, for in Jan., 1940, the United States Federal Food and Drug Administration put into effect a ruling making it obligatory to print on the label of laxative drugs a warning statement regarding their injurious use.

The Press, the Radio, Lectures, etc.

The education effort included many other methods and instruments, such as the distribution of news releases, the preparation of radio scripts and the use of radio stations, the furnishing of lecture outlines, with statistical data and case experience, and the encouragement of talks to lay groups of many kinds throughout the country. Here again there came in the active co-operation of the medical profession, as these talks were usually given by local physicians—often medical examiners of the company, urged to take an active part in the programme by the company's Medical Division. Groups addressed included women's clubs, parent-teacher associations, community and service clubs, employee groups, schools, churches, etc. In nearly 300 of the company's district offices, where groups of agents are employed, the agents were addressed by the company's medical examiners, stressing the vital points in the programme and urging active participation in this activity for the benefit of the policy-holders. At the same time special articles appeared periodically in the company's "Statistical Bulletin," which goes monthly to thousands of physicians, surgeons, educators, health authorities, public officials, and others.

Conclusion

This experience as a whole seems to stand out in support of the value of health education. It encourages the belief that organized effort to instruct the lay public, including those with comparatively little economic and educational advantage, can be productive of concrete results. Success depends on the use of a few simple facts, forcibly and dramatically presented. It involves the co-operation and co-ordination of many agencies and influences, and the use of a variety of approaches. Experience seems to demonstrate a degree of cause-and-effect relationship between an educational programme and a contemporary improvement in the fatality rate from appendicitis, augmented by therapeutic advances as well.

It may be added that this experience is another seemingly clear-cut demonstration that "public health is purchasable," and that purposeful, timely, and specifically "aimed" investments in this field produce definite, measurable, and substantial returns.

EFFECT OF THE *p*H OF THE BLOOD ON HAEMOLYSIS

WITH SPECIAL REFERENCE TO BLACKWATER FEVER

BY

FELIX SMITH, M.D.Birm., M.R.C.P.Lond.
Lieut.-Col., R.A.M.C.

AND

R. WINSTON EVANS
Captain (Pathologist), R.A.M.C.; Research Fellow in Haematology, Christie Hospital, Manchester

The Problem of Intravascular Haemolysis

In the course of observations on 16 subjects of blackwater fever, of whom 5 died and 11 recovered, we were naturally faced with the problem of the arrest of the haemolysis. This is of course the basic problem in all the acute haemolytic diseases, and very little is known about it. Many haemolytic toxins and poisons are known, but in no haemolytic disease has the haemolysin been isolated. In other diseases, notably paroxysmal haemoglobinuria and march haemoglobinuria, the factors which precipitate the breakdown are known (such as the influence of cold and syphilis in the former, and severe muscular strain in the erect position in the latter). We know, of course, that chronic malaria certainly, and big doses of quinine almost certainly, are the precipitating factors in blackwater fever, but we still do not know why in one case these factors produce the fever and in another do not.

Experimental Work

We have made a few observations which shed some light on the problem of the wide diurnal variation in the fragility of red blood corpuscles and the relation between the fragility and *p*H. We have shown that the fragility of red blood cells is capable of changes within very wide limits and can vary from hour to hour. Furthermore, our experiments have proved that the red cell fragility is increased in blackwater fever at the onset, and that this is due, in part, to a lowering of the *p*H of the blood. It should be noted that Israëls, working on paroxysmal haemoglobinuria, also observed that a low *p*H is connected with attacks of haemoglobinuria in that disease, but he does not connect this with alterations in the red cell fragility. The method used in these experiments on fragility was quantitative, the blood being diluted 1 in 200 in 0.4% saline in a haemocytometer pipette, and the number of cells remaining counted after half an hour in the counting chamber.

The first observation was that one subject showed wide variations if tested at different times on the same day. Counts were therefore done at close intervals throughout a 24-hour period, on both healthy and malarial subjects, and it was found that in all subjects there was a wide variation in red blood cell resistance. Examples are 600,000 at 8.30 a.m. and 2,850,000 at 2.30 p.m., 770,000 at 10.15 a.m. and 4,450,000 at 3 p.m., without change in the total red cell count. The period of increased resistance is from 11.30 a.m. to 8.30 p.m., with a peak at 3 p.m., and during the night the resistance remains low throughout. The red cell fragility is increased in blackwater fever—that is, the variations are below the limits observed in normal subjects.

One example of a physiological variation may be given in full:

Time	Cells Unhaemolysed	Time	Cells Unhaemolysed
8 30 a.m.	940,000	8 30 p m.	1,280,000
9 30 ,,	762,000	10.0 ,,	920,000
10 30 ,,	1,950 000	11 30* ,,	1,740,000
11 30 ,,	2,200,000	1.0* a m	1,055,000
1.0 p m.	2,150,000	2.30* ,,	920,000
2 30 ,,	2,460,000	4 0* ,,	980,000
4.0 ,,	1,560,000	5 30* ,,	923,000
5.15 ,,	1,485,000	7 0 ,,	1,500,000
6 30 ,,	885,000	8 30 ,,	1,300,000

*Sleeping.

All possible factors of experimental error were considered and excluded, and the experiment was repeated until we were satisfied of the constancy of the result. A rigid technique was observed throughout the series of experiments, which were carried out only with CO_2-free solutions. It was found that the variations in fragility were unaffected when the tests were made in the incubator at 37° C., at room temperature, and on ice.

Dacie, Israëls, and Wilkinson (1938) have shown that the red blood cells in cases of haemoglobinuria are susceptible to a haemolysin of unknown nature, present in normal serum, which exerts its greatest effect between *p*H 7 and 7.2. They have also shown that during sleep the *p*H of the blood is decreased. It therefore occurred to us that the increase in fragility which had been observed during the night hours might be related to this lowering of the blood *p*H. Experiments *in vitro* were done, using a 0.433% solution of saline buffered to the *p*H levels of 6.8, 7.5, and 8.2. The results obtained were: (1) At the lowest *p*H the cells were more fragile, as judged, not only by the number of cells surviving but also by the wide difference in size and shape. These cells were all markedly spherical and swollen, and their appearance suggested that they were almost at the point of haemolysis. (2) At *p*H 7.5 intermediate figures and appearances were observed, and (3) at *p*H 8.2 all the surviving cells were singularly healthy and normal in appearance. The actual numbers of surviving cells counted at these levels depended, of course, on the time of day that the experiment was performed. (This work is being continued.) The application of these results to the treatment of blackwater fever is discussed under "Treatment."

Certain Clinical Features of Blackwater Fever, based on Personal Experience

The remarks that follow are based entirely on personal observations, and we are quite aware that more extensive experience might well lead to a modification of some of the views expressed.

Blackwater fever can be considered as an intense haemolytic anaemia of sudden onset, occurring in association with malignant tertian malaria. The mechanism of the haemolytic process is not known, but it is thought by many that the haemolysin results from some metabolic breakdown which is precipitated by the administration of quinine or synthetic quinine substitutes. Lysis of the corpuscles occurs, with liberation of oxyhaemoglobin into the plasma. This is converted into methaemoglobin and other pigments. Fairley and Bromfield (1937, 1939) have shown that the serum contains oxyhaemoglobin, methaemoglobin, and methaemalbumin. This last pigment has a large molecule, is impermeable to the kidney, and is never found in the urine.

The appearance of the urine in blackwater fever is characteristic. It is of a port-wine colour, with a pinkish froth on shaking. A heavy brownish sediment collects on standing. Albumin is present, and microscopy shows absence of cells. Later in the course of the disease, when some renal necrosis may have taken place, a few red and white cells may be present.

Clinically, blackwater fever in our experience presents certain differences from the disease described in the textbooks as occurring almost exclusively in "old coasters" with a long history of numerous attacks of self-treated subtertian malaria. Our cases have all been in unusually good types of soldier, which, from the Army point of view, made their recovery all the more important. In only one case was there reason to suspect carelessness in the taking of suppressive quinine, and this case also had the greatest number of attacks of malaria —five: the other patients were regular quinine-takers and were in good general condition. Alcoholism, venereal disease, dysentery, and lack of a reasonable standard of education were not factors in this group of cases. The "pre-blackwater" state as described in the textbooks was not present. The statement made in some books that the disease is almost confined to light-haired men was also found untrue for our cases. In fact, we think the majority of these cases—certainly the last five—were of the type with black hair, rather pale complexion, and brown eyes.

The onset of all our cases of blackwater fever was characterized by a rigor. This is worth mentioning because definite rigors occur in less than a third of our series of cases of subtertian malaria. The only unusual symptom preceding the rigor was a sense of intense general fatigue for two or three days. After the rigor vomiting was a constant feature, and these three symptoms—fatigue, rigor, and vomiting—should lead to careful examination of the next specimen of urine. It is essential to examine it microscopically before making the final diagnosis. Acute pyelitis, with an unusual degree of haematuria, associated with acute bacillary dysentery, imitated the onset of blackwater fever in one case, and illustrates the importance of microscopical examination. When blackwater fever occurs during quinine treatment of an attack of subtertian malaria it often does so on the third or fourth day. It is safer to give the quinine hydrochloride in six doses of 5 gr. than in three of 10 gr. Quinine must of course be stopped completely if blackwater fever occurs. Slight jaundice associated with albuminuria is also an indication for stopping quinine. In treating malaria the urine should be rendered alkaline as a routine and the patient kept in bed. Cases of blackwater fever should not be moved unless circumstances make this absolutely essential. It is tempting at the onset to send these patients to hospital, as their general condition is often quite good; but within 36 hours they become extremely pale and obviously too ill to move. Very deep jaundice did not occur in any of our cases, but a lemon-coloured tinge appeared on the first day and deepened as the haemolysis continued.

It has been calculated that a man may lose the equivalent of 4 to 6 pints of blood by intravascular haemolysis in 36 hours in this condition. The liver, like the reticulo-endothelial system generally, has an enormous capacity for dealing with liberated haemoglobin by splitting haematin into bilirubin and haemosiderin, the first being excreted in the bile and the second being stored, chiefly in the liver and spleen. The appearance of haemoglobin in the urine is therefore an indication more of the rapidity of the breakdown than of its extent. Nevertheless, at best it means the loss of several pints of blood, and the condition is comparable (but not exactly similar) to that of traumatic haemorrhage. The pallor and sweating and the thin running pulse are very similar to those of wound shock, and the general treatment has much in common with that of shock. The factor which is absent is that of the effects of a wound—with the possibilities of sepsis, absorption of products of tissue breakdown, etc. The factor which is present in blackwater fever and absent in traumatic haemorrhage is that of the rapid accumulation of the breakdown products of intravascular haemolysis and the serious damage which can result to the kidneys from attempts to excrete these products.

The older theory that the chief, and likeliest, cause of kidney damage is the accumulation of crystals of acid haematin in the tubules is now largely discarded. Sections of the kidney show microscopically that the tubules are blocked, but it seems more probable that this material is a plug of methaemoglobin, with the debris of broken-down red blood cells and damaged renal-tubular cells, etc. It is possible that the first step in this process is the early degenerative change in the epithelial lining of the tubules due to the severe anaemia, with resulting nutritional deficiency of these cells. That the cells lining the glomeruli are much less and much later affected may be taken as supporting evidence of this theory, since these cells receive a more plentiful blood supply than do those lining the tubules. However this may be, the fact is that the tubules do tend to become blocked, and one of the most important points in treatment is to prevent this blocking. We therefore should consider the factors causing this renal obstruction, and how they can be avoided or minimized. These factors are: (A) the pigments and cellular debris resulting from continued haemolysis; (B) the tendency of these products to obstruct the renal tubules; (C) the severe degree of anaemia, damaging the kidneys' excretory function; (D) the production of acid haematin crystals in the kidney tubules; (E) the existence of living subtertian malarial parasites in the blood.

Treatment of Blackwater Fever

Factor A

The first problem in treatment, therefore, is how to check the haemolysis. The application of the results of the experimental work on fragility mentioned above is obvious. Alkalis must be given in such amounts as actually to increase the *p*H of the blood plasma. The value of this was most strikingly illustrated by two of our cases. In the first an attack of tetany, with a major convulsion, occurred after administration of 2% sodium bicarbonate in normal saline by slow intravenous drip. This patient passed clear urine immediately afterwards and the haemoglobinuria never recurred; his general condition also improved considerably and the attack of tetany appeared to be the turning-point to recovery. He was a young man whose acid-alkali balance was easily upset. During his attack of tetany the *p*H of the blood would be raised well over normal physiological limits, and the effect was presumably to raise the resistance of his corpuscles and cause the haemolysis to cease. In a second case the urine had become clear and remained so for 36 hours, when a recurrence of haemoglobinuria occurred in two specimens. Alkalis were given in concentrated form (3M sodium lactate 40 c.cm. intravenously and 60 g. each of sodium bicarbonate and sodium citrate by mouth). The next specimen was clear, and the proof of hyperalkalinization was to be seen in the production of Trousseau's sign when a sphygmomanometer was applied to the arm.

For the prevention of haemolysis and the rendering of its products as harmless as possible we have given alkalis by mouth as follows: Sod. bicarb. gr. 20, sod. citras gr. 20, aq. ad 1/2 oz.—two-hourly, or double that dose four-hourly. This is not a particularly high dosage, but there is another and most important means of alkalinization at our disposal—the use of 2M or 3M solutions of sodium lactate intravenously. As a routine 20 c.cm. of this solution has been given three times a day at equally spaced intervals, using a 20-c.cm. syringe and a fine hypodermic needle. In our opinion double this dose might easily be used with advantage. It can be made up in a saturated solution of sodium bicarbonate, but without the latter it has the inestimable advantage of being sterilizable by boiling, and since a saturated solution of sodium bicarbonate is only about 11%, the amount thus given is small, and we have discontinued its inclusion. Intravenous administration of concentrated solutions of sodium lactate is strikingly effective in producing rapid alkalinization and stopping haemolysis. It has, however, the disadvantage of causing thrombosis of veins, and one should therefore avoid the use of veins which may be needed later for blood transfusion.

Factor B

The problem of ridding the kidneys of the products of haemolysis is met by the intake-and-output balance of fluid. In the Tropics sweating is responsible for perhaps half of the excretion of the intake of fluid by mouth and thus tends to concentrate the urine. Sweating therefore is a danger in blackwater fever, and the nurses should be instructed to keep the patient's skin cool: we have always ordered tepid sponging to reduce temperatures surpassing 103° F. At the onset nearly all the cases show an excretion of urine of two-thirds of the intake of fluid by mouth, and this is quite satisfactory. We have become concerned only when the output has fallen below half the intake. It is a point in prognosis that cases showing a poor excretion from the start have a poor chance of recovery; and, conversely, patients in whom the output of urine remains high in quantity still have a good chance of recovering even though the urine remains dark and bloody and the blood count falls below 2,000,000 cells.

The administration of fluid by mouth probably cannot be overdone, but, from the evidence of a fatal case, it can be easily overdone by intravenous drip administration. This case developed oedema of the dependent parts, and on performing the necropsy the tissues throughout the body were found to be saturated and swollen with water. The excretion of water is the function of the healthy kidney, and to pile up the "head" of water behind the kidney in the hope of "flushing out" that organ is unscientific. It is much more reasonable, in our opinion, to try to sustain the efficiency of the kidney by attending to its nutritional needs—i.e., by the judicious use of blood transfusions. This is referred to under the next heading. On this question of excretion a final word may be said on the subject of uraemia. One of our patients certainly died of acute kidney failure. We gave the orthodox treatment, which is really an attempt to make the kidney and bowel take over the excretory functions of the kidney; but it is probable that by so doing we only made bad worse, by concentrating the urine and increasing the already extensive blockage of the renal tubules.

Factor C

The blood picture at the onset is invariably characterized by a considerable degree of anaemia. A typical series of red cell counts is as follows: 3,500,000 at the onset, 2,800,000 after 24 hours, 2,200,000 after 48 hours (the urine is often clear by this time), 1,800,000 after 72 hours. The fall in haemoglobin percentage is parallel with that of the red cells, and a colour index of unity is maintained, using mean standards.

During the stage of haemolysis the leucocyte count was invariably found to rise, a relative and absolute increase in monocytes being responsible: in one case the monocyte count was 47.5% of the total leucocyte count of 18,000. They are presumably liberated to deal with cell debris, such as "ghost" red corpuscles. The bone-marrow picture is that of a normoblastic hyperplasia, the majority of the normoblasts being of a large variety showing early eosinophilic staining reactions. At a later stage in the disease—i.e., during the recovery period—these are replaced by a smaller form of normoblast with an intensely basophilic cytoplasma, probably indicating an acute iron deficiency. As the haemolysis abates there is a marked fall in the number of circulating leucocytes, and in three of our cases a leucopenia (in the region of 4,000) developed.

Treatment of the anaemia is therefore mainly the administration of iron, and the iron salt at our disposal was ferri et ammon. cit., which was given in a dose of 30 gr. t.d.s. This was started very soon after the urine had cleared. In order to make sure that no dietetic deficiency should slow up the response of the bone marrow it was our practice to give liver extract intramuscularly at the same time.

In some cases of blackwater fever there is a tendency for a slow marrow response, and the haemolytic toxin responsible for the disease may possibly exert a toxic effect on the marrow. In one case alarm was felt at the possibility of a marrow aplasia occurring. In all cases the total red cell count does not begin to rise until three clear days after haemolysis has ceased, and it may be as long as six days. It must not be forgotten that the fact that the urine has ceased to contain haemoglobin does not mean that haemolysis has ceased. It may be going steadily on—and when parasites persist and the temperature remains up, haemolysis certainly is going on, just as it does in any severe case of subtertian malaria.

A good deal of attention has recently been paid to blood transfusion in blackwater fever and many papers have been published on it. It is almost universally praised, and some authors advocate frequent transfusions of whole blood from the onset of the disease. Our own experience has caused us to modify this view; we now regard the problem as follows:

Blood transfusion would be of tremendous value if the normal plasma given contained any antihaemolytic substances which would cause the intravascular haemolysis to cease. In fact, in our experience there is no evidence that it does so. This would not matter much if it were not that blackwater fever patients seem to be particularly liable to violent reactions during or after the transfusion—especially in the first two days. This may be connected with the tendency to acidaemia, and is therefore a further reason for early and thorough alkalinization. The problem of compatability is particularly acute in blackwater fever, and cross-matching—both ways—is essential. Moreover, the suspensions of cells should be tested not only at room temperature but also on ice in an ice-box for a full 24 hours. It often happens that out of a dozen donors, all of the same group as the patient, only one or two—and sometimes none at all—are really compatible when subjected to this stringent test. Even when one is found, unpleasant reactions have occurred during transfusion, and the best method is probably to give minute quantities, and to give them slowly—e.g., 20 drops in the first ten minutes, after which the transfusion may be proceeded with more quickly.

For these reasons we have given up using blood transfusions in the first two days. We, however, acknowledge their great importance in preventing a profound anaemia from developing, and when the red cell count is steadily falling and is approaching 2,000,000 a pint of blood should be given. It is useful to remember that whenever a needle is safely fixed in the patient's vein, for either blood or sodium-bicarbonate-and-saline transfusion, the opportunity is present to add slowly 20 or 40 c.cm. of the concentrated sodium lactate solution mentioned above.

Transfused red blood cells undergo intravascular destruction just as do the patient's own cells, and for this reason alone it seems wise to avoid transfusions in the early stage of the disease, when, as previously noted, our efforts should be directed at checking—not increasing—intramuscular haemolysis.

Factors D and E

The question of preventing the formation of acid haematin crystals has already been mentioned, and it suffices to say that the high degree of alkalinization advocated will certainly prevent this happening.

Finally, there is one aspect of blackwater fever which tends to be forgotten. In the constant watch which must be kept over the intake and output, the reaction and appearance of the urine, the blood picture, and so on, we are apt to forget that the patient is suffering from a severe attack of subtertian malaria. It is an attack, moreover, which cannot be treated by quinine or quinine substitutes. High temperatures on the first, third, and fifth days are therefore not a matter for surprise, and an attack of typical malaria is common enough about 10 days after the blackwater has ceased. In one case parasites persisted in the blood from the onset of the disease; the urine cleared up, but the temperature persisted; and finally, 14 days after the onset, the patient died of cerebral malaria. Looking back on this case, it is now felt that we should have given quinine courageously instead of in the minute doses we used. Our present plan is to give a half-tablet of mepacrine 48 hours after haemoglobinuria has ceased. If no ill effect ensues we give a half-tablet twice a day for a week, and thereafter two tablets every Sunday and Wednesday in the approved "suppressive" manner.

Discussion

This paper claims that the fragility of red blood cells varies considerably throughout the 24-hour period. Further, it advances the theory that the *p*H of the blood plasma is the factor responsible for these alterations in fragility and claims that this is demonstrable *in vitro*, using solutions of saline varying in *p*H from 6.8 to 8.2. An immediate criticism is that the *p*H of the blood plasma never varies to anything like this degree; and a second criticism might be that *p*H estimations of the blood were not done at the same time as the fragilities were estimated. This latter procedure was not possible—to the necessary degree of accuracy—owing to the conditions under which the work was performed. The former objection is perhaps fairly met by the assumption that in cases which developed clinical tetany the plasma *p*H actually would approach 8.

Case reports have not been included in detail, and a short account of the series should therefore be given. The original 10 cases were seen by one of us (F. S.) and treated on the lines given by the textbooks. It is well known that blackwater fever varies in severity from place to place and in different years. Three consecutive deaths occurred early in the series, and it was realized that we were confronted by a particularly bad type of the disease. In the cases numbered 7 to 10, therefore, an attempt was made to improve this high mortality by using early and repeated blood transfusions—a method which has been advocated with enthusiasm in recent years. In only one case did we feel satisfied that this procedure saved the patient's life. In the other cases blood transfusion was clearly not without its dangers, even though the greatest care was exercised in matching.

Cases 11 to 16 occurred in a different colony, where laboratory conditions were considerably better. The second of these cases coincided with the observation of the variation of fragility of red cells. It is referred to earlier on in this paper as the case in which tetany occurred followed by cessation of haemolysis. The suggestion that alkalaemia was responsible for this was obvious, and led to the experimental work *in vitro* which confirmed this. Cases 13, 14, and 16 were treated successfully by the method described, enough alkali being given to produce Trousseau's sign. Cases 10 and 15 both had suppression of urine from the onset and died of uraemia.

The final case illustrates the points which it is desired to bring out, and the following notes are therefore included:

Case Notes

B. H., British, aged 24; 14 months' service in Tropics. Blood group O. Admitted 9 p.m. Sept. 28, 1942.

Previous History.—In U.K., no serious illness. In the Tropics: General lassitude for three months; headaches for four weeks; no temperature, sweating, shivering attacks, or other symptoms to suggest malarial infection. He has been sleeping within a few hundred yards of a native village. He observes antimalarial precautions and takes a daily dose of quinine hydrochloride 5 gr. Occupation, indoor and sedentary. For three months has been on duty three nights each week, but does not remember being bitten by mosquitoes. Smokes 20 to 30 cigarettes and has one or two bottles of beer a day. Walks about two miles daily.

History and Progress.—An attack of shivering, followed by sweating, occurred on the evening before admission. On Sept. 28 he complained of headache and pains in the joints and muscles of legs and arms. Felt hot and sweated freely, and in the late afternoon vomited seven times in two hours. Bowels opened normally. Temperature 103.8°, pulse 124, respirations 18. Spleen enlarged 1 in. below left costal margin. The skin over the chest and back affected by prickly heat. No signs of anaemia, jaundice, or oedema. Herpes labialis not present. Conjunctivae suffused. Urine dark in colour but contained no albumin; reaction acid. Examination of all systems showed no sign of disease other than the splenic enlargement and the existence of an attack of subtertian malaria. On admission given potass. citras and sod. bicarb. āā 30 gr., and nursed in blankets.

Sept. 29.—Blood film positive for parasites. Quinine hydrochloride 10 gr. b.d. Alkalis as above t.d.s.

Sept. 30.—Felt well. Temperature 100° at 7 p.m. Treatment continued, with quinine increased to 30 gr.

Oct. 1.—Felt well. Bowels open twice. Urine alkaline to litmus. Temperature normal until 7 p.m., when it was 99.6°.

Oct. 2.—At 3 a.m. vomited. Got up and passed "dark-coloured" urine, which was not saved. Returned to bed without reporting this. Awakened at 5 a.m. feeling shivery. Urine again passed, and later reported as containing "haemoglobin, albumin, much debris, occasional epithelial cells, and very occasional erythrocytes." It was alkaline in reaction. Conjunctivae and skin showed slight jaundice. Liver and spleen tender on palpation. At 6 a.m. temperature 100.2°, pulse 86. Treatment by abundant fluids and alkalis started immediately. Quinine stopped. 8 a.m.: night urine was 7 oz. plus one lost specimen. Fluid taken by mouth, 31 oz. 8.15 a.m.: 3M sodium lactate 40 c.cm. intravenously. 11 a.m.: Hb 60%; R.B.C. 4,000,000; W.B.C. 6,000—polymorphs 62%, lymphocytes 28%, monocytes 10%. 12.45 p.m.: Complained of aching pain in lower abdomen, accentuated after passing urine. 1.50 p.m.: B.P. 120/80; 3M sodium lactate 20 c.cm. intravenously. 7.20 p.m.: 3M sodium lactate 40 c.cm. intravenously; carpal spasm present on application of pressure to arm. 8 p.m.: Intake of fluid since 8 a.m., 155 oz. by mouth plus 12 oz. alkaline mixture (360 gr. pot. citras, 360 gr. sod. bicarb.) plus 100 c.cm. sodium lactate solution intravenously; urinary output, 80 oz.; the urine remained "black" throughout the day. 8.45 p.m.: A slight rigor; complaint of cramps, and jaw felt stiff; Trousseau's sign easily elicited; specimen of urine definitely lighter in colour.

Oct. 3.—2.55 a.m.: Urine practically normal in appearance. 4.55 a.m.: A "black" specimen of urine. 8 a.m.: Urine again normal in appearance. Since 8 p.m. on Oct. 2 intake of fluid has been 128 oz.; output of urine, 58 oz.

Later details show a rapid improvement in urinary output and there was no further haemoglobinuria. Blood examinations on Oct. 3 showed Hb 50%, R.B.C. 2,500,000; and on Oct. 4 Hb 45%, R.B.C. 2,500,000—illustrating the rapidity with which a severe degree of anaemia may be reached. There was gradual improvement on the succeeding days.

Summary

Certain aspects of the pathology and treatment of blackwater fever are discussed. An account is given of experimental work which shows that the fragility of red blood corpuscles is increased at low *p*H levels and decreased at high levels. A new rationale for the treatment of intravascular haemolysis is therefore suggested, and the methods of giving alkalis are described. The value of intensive alkali therapy is illustrated by reference to cases. A discussion on the clinical and haematological features of blackwater fever is given, with an account of the treatment.

DELAY IN DIAGNOSIS AND SANATORIUM TREATMENT OF PHTHISIS

BY

BERTRAM MANN, B.Sc., M.D., D.P.H.

Consultant Tuberculosis Officer, West Riding C.C. of Yorks

It is generally accepted that delay occurs before the diagnosis of pulmonary tuberculosis is established. Most authors are agreed that part of this delay is due to the development of tuberculosis in the absence of symptoms. For this reason mass radiography has been advocated for the detection of the early asymptomatic case (N.A.P.T., 1942, and others). Following this period of early or latent disease there is a phase in which the signs or symptoms may or may not suggest phthisis. Indeed, there is such a wide variety of non-specific symptoms that the condition may often be erroneously diagnosed as anaemia, debility, bronchitis, influenza, atypical pneumonia, etc. It is with this latter phase—the phase of partially defined signs and symptoms—that this paper is concerned.

The Investigation

A total of 300 patients, consisting of 165 males and 135 females, were investigated. A careful history was noted, with especial emphasis on haemoptysis, pleurisy with and without effusion, a recent history of contact (two years) associated with debility, and a loss of weight of over 4 lb. associated with debility. These symptoms and signs were taken as criteria because, while not pathognomonic, they can be regarded as strongly suggestive of phthisis. In each case the total period of delay from the time those "suggestive" signs or symptoms occurred until the date of admission for sanatorium treatment was analysed under three headings. (1) Time-lag elapsing between suggestive signs or symptoms occurring and the patient's seeking medical advice from his practitioner; (2) time-lag elapsing between the patient's seeking medical advice and being referred by his doctor for consultant or dispensary opinion (or notified by the practitioner himself); (3) time-lag elapsing between the patient's first dispensary consultation and his admission to sanatorium for treatment.

In this way some attempt was made to ascertain statistically where the principal delays in final diagnosis took place after it could *reasonably* have been established. The average total delay between suggestive symptoms occurring and admission to sanatorium was found to be 9.27 months. Of this, 3.64 months was the average delay before the patient with suggestive symptoms consulted his practitioner. A further average of 3.28 months occurred before the patient was referred for dispensary or consultant opinion; and a final delay averaging 2.35 months took place before treatment was initiated in sanatorium.

Those time-lags were then classified according to age and sex groups, with the following results.

TABLE I

Age Group (years)	Males		Females	
	No.	Average Time-lag before Patients consulted Practitioner (months)	No.	Average Time-lag before Patients consulted Practitioner (months)
5–9	1	0	0	0
10–14	0	0	1	0·75
15–19	14	1·58	18	2·097
20–24	25	2·5	33	3·0
25–29	31	2·92	28	3·95
30–34	26	3·26	21	3·88
35–39	19	4·17	17	5·12
40–44	17	3·63	8	6·55
45–49	9	3·56	5	7·33
50–54	11	3·27	1	7·0
Over 55	12	8·0	3	4·66
Totals	165	3·42	135	3·90

There was an average delay of 3.9 months in females and 3.42 months in males before consulting their own practitioner. In almost every age group this delay was more prolonged in females. Furthermore, there was a progressive increase in the period of delay shown by every female age group up to 50–54 years of age. A similar delay in seeking medical advice was noted in males up to 39 years of age.

Results

Haemoptysis.—In the course of investigating 300 histories, haemoptysis was found to be present on 101 occasions—i.e., 33.6%. Fishberg (1919) in this regard says: "Happy, then, is that patient who suffers an early haemoptysis, for this usually ensures early examination. It is doubtless on account of its startling character that an initial haemorrhage has earned a reputation as a good prognostic sign." A somewhat more cautious attitude is taken by Ellman (1940), who states that haemoptysis is "a fortunate accident from the patient's point of view in that a dramatic manifestation enforces him to undergo early treatment . . . or at some period of the tuberculous course." Lloyd (1940) goes even further, and suggests that haemoptysis "occurs as the earliest symptom in only a small percentage of cases, but each case calls for the fullest investigation." The average time-lag in the 101 cases showing haemoptysis was 3.64 months before such patients consulted their own practitioner. A further delay of 2.64 months occurred before the patient was referred by his own doctor for consultant opinion or before a final diagnosis was made. Thus, on the whole, haemoptysis does not appear to suggest to the patient an earlier visit to his doctor, and the patient's practitioner sends a case only 0.6 month earlier than the "ordinary" case (i.e., a case revealing any of the four significant signs or symptoms taken as suggestive of phthisis) for dispensary investigation.

Pleurisy.—A history of idiopathic pleurisy was noted in 129 cases (43%). This compares with Fishberg's figures of 30–40%, Pierce's 35% and 52% in two series of investigations, and Meachen's (1941) 13.8%. In 92 out of the 129 patients there was definite evidence of effusion, which was confirmed by radiological findings or aspiration. The remaining 37 had a history of "dry pleurisy," which diagnosis had been made by the practitioner in charge. In this condition the average time-lag before the patient attended the doctor for investigation was 3.07 months, and before being referred to the dispensary for consultant opinion a further 3.3 months elapsed. Thus in pleurisy both patient and doctor appear to have called for earlier examination than in the case of all the other symptoms or signs here considered as suggestive of pulmonary tuberculosis.

Sputum.—An analysis was made of the 300 cases with special reference to the frequency with which sputum examination was carried out by the patient's own doctor. The results are noted in Table II.

TABLE II (*300 Cases*)

No sputum present for examination	50
Sputum sent by practitioner for examination	54
Sputum not forwarded by patient for examination	1
Sputum present but not examined by practitioner	195

Thus, in only 22% of cases was sputum sent for examination by the patient's own doctor.

Family or Contact History associated with Debility.—In 99 cases there was a history of contact associated with general debility. Of this total, "exposure" outside the intimate family circle—viz., father, mother, brother, sister—occurred in 14 cases. In the remaining 85 contact took place in the same household. Beal (1940) noted 30% of his cases as showing a contact or family history, and Lloyd and Macpherson (1936) in a series of 1,000 young adults found that 39.6% had a history of contact.

Loss of at least 4 lb. in Weight associated with Debility.—Of the 300 cases 206 gave a history of a loss of at least 4 lb. in weight associated with debility.

Discussion

The object of the present survey was to determine the duration of the delay before patients suffering from symptoms "suggestive" of phthisis received sanatorium therapy. The reasons for the patient's delay before seeking medical advice are not difficult to appreciate. Antagonism to the medical profession born of ignorance and fear pervades almost all sections of society. There appear to be immense possibilities for education and intelligent propaganda among the public on the lines indicated by the N.A.P.T., with especial emphasis on the education of females in the middle-age group of the population. How far the possibilities of propaganda have been neglected is seen in the tardiness with which patients with haemoptysis or pleurisy consult their own practitioners.

So far as the general practitioner is concerned there is room for more rapid diagnosis. According to Varrier-Jones (1933) the reason is because "in the first place the vast majority of students qualify and enter practice without seeing possibly a single early case of infiltration. They are thus unable to detect tuberculosis at its onset." This view is held also by Gregory Kayne *et al.* (1939). There seems to be a strong case for better education in tuberculosis in both the undergraduate and the postgraduate stages of medicine. A student residency in a sanatorium is advocated by Nelson (1939), but it would appear preferable that such a period of time should be spent examining the early cases of phthisis which are to be seen at the dispensary.

In patients with a history of haemoptysis there should be no further delay by the practitioner before the case is notified or is referred for specialist examination. In a number of instances "streaks" of blood in the sputum were not regarded as "suggestive" of phthisis.

Again, after an attack of pleurisy, there should not be a further delay before the case is satisfactorily diagnosed. This delay is needless, because, as Burrell (1937), Wynn (1940), Maxwell (1941), and others have suggested, in all cases in which acute pleurisy appears to be "primary" it is well to assume that the cause is tuberculosis unless definite proof of some other cause is forthcoming. There is much to be said for the opinion which urges that "primary" or idiopathic pleurisy should be made a non-specific notifiable disease which could be referred to a chest or tuberculosis dispensary for observation and final diagnosis. This would avoid the danger of branding some non-tuberculous pleurisies as phthisis and would close the avenues whereby such cases escape consultant opinion. At the same time the general practitioner would have the satisfaction of having been instrumental in finding a potential case of pulmonary tuberculosis.

Sputum.—As already observed, sputum was sent for examination by the patients' doctor in only 22% of the 250 cases in which it was present. This suggests that practitioners fail to make use of the existing free public health facilities for the examination of sputa—a failure that may in some measure be responsible for the delay in diagnosis.

Sanatorium.—The time-lag which elapsed between a patient's being notified or referred to the tuberculosis dispensary and his admission to sanatorium is to some extent a reflection on wartime conditions. In part these deficiencies appear to be due to the inadequacy of both nursing and domestic personnel in fulfilling the needs of the sanatoria (Heaf and Rusby, 1942; Snell, 1942). The corollary is that serviceable wards in satisfactory condition are out of use because of staff difficulties while patients clamour for admission. Another factor is the lack of sanatorium beds in certain areas of the country owing to "blocks" being reserved exclusively for the boarding of troops. Moreover, the existing problems have been accentuated by the wartime rise in the incidence of phthisis.

History of Contact associated with Debility.—Of the investigated cases 99 (33%) were noted to have a history of phthisis associated with debility. Thus the field of contact examination appears to provide an early and very fruitful means of finding cases.

General.—It should here be stressed that such measures as are suggested for the limitation of delay in the diagnosis of pulmonary tuberculosis and the initiation of sanatorium therapy are on no account an alternative to mass radiography. They merely re-emphasize certain well-established principles in case-finding, with a plea for their application to the public and all branches of the medical services.

Summary

Three hundred cases of phthisis were investigated with special reference to the time-lag occurring before treatment at sanatorium was started and after symptoms "suggestive" of phthisis had been established. The delays were classified according to age and sex. Particular note was taken of the delay in diagnosis following pleurisy and haemoptysis. The number of sputa sent for examination by practitioners was the subject of analysis. The following reforms are advocated.

1. A more generous plan of public education on tuberculosis on the lines pursued by the National Association for the Prevention of Tuberculosis.
2. A revision of existing undergraduate and postgraduate medical teaching, with greater emphasis on the "early" case.
3. The notification of pleurisy (primary or idiopathic) as a non-specific disease, with facilities for the reference of such cases to the tuberculosis or chest dispensaries for a more adequate and final diagnosis.
4. The more extensive employment of existing public health facilities for sputum examination.

I wish to record my thanks to Doctors H. Raeburn, V Ryan, R. Watson, and especially Dr. G. S. Johnston of the Tuberculosis Department of the West Riding C C., for permission to publish this investigation and for their assistance.

LYMPHADENOMA AND LEUKAEMIA

BY

A. WILSON GILL, M.D.Ed., M.R.C.P.
Honorary Physician, North Staffordshire Royal Infirmary
AND
A. J. McCALL, M.D.Liverp., M.R.C.P.
Pathologist to the Infirmary

There are many evident clinical similarities between lymphadenoma and the leukaemias, and the suggestion has been made that a close relationship exists between these diseases. This suggestion is supported by the observation that occasionally both may occur in the same patient. The case now described appears to have been such an example.

Case History

A girl aged 18, unmarried, was first seen in April, 1940, complaining of general weakness, enlarged glands on both sides of the neck, in the right axilla and the left groin, with attacks of suffocation and dyspnoea at night suggesting mediastinal involvement. The spleen was not palpable. A blood count showed: Hb, 82%; R.B.C.s, 4,450,000; C.I., 0.92; W.B.C.s, 9,375—polymorphs 58%, lymphocytes 38%, monocytes 1%, eosinophils 3%. The family history disclosed that the patient's two sisters had died in infancy from unknown causes, and the mother suffered from anaemia of undetermined type

Radiographs of the patient's chest revealed a mass surrounding the aorta in the upper mediastinum. A supraclavicular gland was removed. This showed the histological features of lymphadenoma. There was reticulum-cell hyperplasia with the formation of numerous Sternberg-Reed giant cells. Eosinophil leucocytes were scattered throughout the gland, and occasional plasma cells were seen. Some areas of the gland were replaced by dense collagen, and in the more cellular areas there was a fine reticular fibrosis.

Treatment by deep *x* rays (Dr. C. Bellamy) resulted in rapid disappearance of the superficial glands, considerable diminution of the intrathoracic mass, and complete relief of all symptoms. Other blood counts revealed no significant alteration. Further irradiation was given at intervals during the next two years, during which period the general health remained excellent.

In March, 1942, a sudden and dramatic change was evident. Extreme anaemia developed. Blood counts were as follows:

April 18, 1942—Hb, 34%; R.B.C.s, 1,650,000; C.I., 1.03; W.B.C.s, 49,800—polymorphs 2.5%, lymphocytes 94.5%, monocytes 0.5%, lymphoblasts 1%, metamyelocytes 0.5%, neutrophil myelocytes 1%. Anisocytosis and slight polychromasia were present. No nucleated red cells were seen. In this and all subsequent counts platelets were very scanty.

May 24, 1942.—Hb, 40%; R.B.C.s, 1,950,000; C.I., 1.03; W.B.C.s, 29,800—polymorphs 0.5%, lymphocytes 98%, lymphoblasts 1.5%. Anisocytosis ++. No nucleated red cells were seen. The only granular cells seen were 1 myelocyte and 1 polymorph.

May 26, 1942.—Hb, 22%; R.B.C.s, 1,270,000; C.I., 0.8; W.B.C.s, 180,000—polymorphs 2%, lymphocytes 75%, myelocytes 1%, premyelocytes 1%, lymphoblasts 20%.

No enlarged superficial glands were found, the spleen was not palpable, no external haemorrhages occurred, and the mediastinal shadow was not increased. There was an irregular pyrexia, which, however, showed no tendency to periodicity of the Pel-Ebstein type. Blood transfusions were given on three occasions with slight improvement. Thereafter deterioration was rapid, with the onset of uterine haemorrhage, which persisted for two weeks despite ergot, progestin, vitamin K (kapilon), and ascorbic acid.

The rapidly developing anaemia associated with scanty platelets and the increasing leucocyte count now seemed to us to establish a diagnosis of acute leukaemia. The high proportion of lymphocytes appearing in the later blood counts suggested that the leukaemia was lymphoid in type. The primitive cells observed were identified as lymphoblasts after supravital staining with janus green and neutral red. The mitochondria thus demonstrated in these cells were large and heavy and of the lymphoblastic type; these cells showed no peroxidase granules. In Romanovsky-stained films the nuclear membrane was well defined and the nucleoli distinct. Of the cells classified as lymphocytes a number showed immature characteristics in that the chromatin pattern was much finer than that of mature lymphocytes and a suggestion of nucleoli was sometimes present. Occasionally Rieder forms of lymphocytes were seen. Smear-cells were not so numerous as is usual in lymphoid leukaemia.

The above observations were regarded as confirming the diagnosis of acute lymphoid leukaemia.

Death occurred on May 29, but unfortunately no necropsy was allowed. Blood films were examined by Prof. L. J. Witts, who confirmed the diagnosis of lymphoid leukaemia. Dr. A. H. T. Robb-Smith examined a section from the lymph gland and confirmed the diagnosis of lymphadenoma.

Previously Recorded Cases

Watson (1938) has fully discussed the association of lymphadenoma with leukaemia. One of the earliest cases in which the diseases were thought to coexist was described by Fabian (1908), who observed myeloid leukaemia and chloroma, with histological changes suggesting lymphadenoma. Dietrich (1912) described his case as showing lymphadenoma and "mixed-cell" leukaemia. More recently Warthin (1931) described six cases of lymphadenoma which ultimately developed the blood picture of lymphoid leukaemia, and two further cases terminating in myeloid leukaemia. McCartney (1928) thought his case showed lymphoid leukaemia, lymphosarcoma, lymphadenoma, and endothelioma, but Ewing (1928) doubted the diagnosis of leukaemia. Hittmair (1928) maintained that transitional forms between lymphadenoma and leukaemia occurred; he described a case of lymphadenoma with "leukaemic reticulo-endothelial reaction."

A case in which the occurrence of lymphadenoma and acute myeloid leukaemia appears to have been quite clearly established was recorded by Skworzoff (1930). The leukaemia responded well to irradiation before the existence of lymphadenoma was discovered. Dubberstein (1931) recorded the simultaneous occurrence of lymphadenoma and subleukaemic lymphoid leukaemia, and a similar case was described by Craver (1936). In two cases cited by Watson (1938) lymphadenoma was observed with a subleukaemic blood picture of lymphoid type, and histological evidence of leukaemic infiltration was found.

Unless the blood is frankly leukaemic the coexistence of the two diseases must sometimes be doubtful in the absence of a necropsy, for it is recognized that a high leucocytosis may occasionally be found in lymphadenoma (Hirschfeld, 1925). A further point requiring notice is that lymphadenomatous lesions in the marrow, which were observed in 50% of lymphadenoma cases examined by Symmers (1924), may cause immature white cells to appear in the blood. In our case there was no necropsy, but we do not think that the blood changes could be regarded as a leuco-erythroblastic reaction.

In some of the published cases both conditions have been present when the patient was first seen, and in others leukaemia has appeared in a patient already suffering from lymphadenoma. It is more difficult to be certain that lymphadenoma has ever developed in a patient suffering from leukaemia. Dietrich (1912) thought this sequence occurred when lymphadenoma was found at necropsy on his patient, who had developed leukaemia 19 months previously. No biopsy was, however, done on this case, and it is possible that lymphadenoma may have existed before the development of leukaemia and escaped detection.

Irradiation Therapy

Forkner (1938) thought there was some evidence that irradiation might be one factor, perhaps in especially susceptible individuals, in the production of leukaemia. The question therefore arises whether the treatment of lymphadenoma by irradiation has any influence in inducing leukaemia in these cases. This possibility cannot be completely excluded, but it may be observed that although irradiation is almost universally used in the treatment of lymphadenoma, leukaemia occurs very infrequently in these cases. It is noteworthy that in six cases of lymphadenoma described by Warthin (1931) leukaemia developed in the absence of radiotherapy, and that Craver (1936) was unable to find any evidence that the development of leukaemia in cases of lymphosarcoma was attributable to irradiation therapy.

Lymphadenoma, Leukaemia, and the Reticuloses

Observations on the pathological processes that may affect the reticulum cell have resulted in the introduction of the term "reticulosis" to include "all conditions in which there is generalized enlargement of the spleen, lymph nodes, and liver, due to hyperplasia of differentiated or undifferentiated mesenchymal cells" (Hadfield and Garrod, 1938). It is clear that the leukaemias and lymphadenoma are both included within this definition, and the close generic relationship between these diseases has been repeatedly and strenuously argued by Warthin (1927, 1928, 1931), and was supported by Pullinger (1932).

In the classification of the reticuloses suggested by Robb-Smith (1938) the leukaemias and lymphadenoma are designated "haemic reticuloses" and "fibro-myeloid reticulosis" respectively. The name "fibro-myeloid reticulosis" had previously been suggested by Pullinger (1932), who pointed out that lymphadenoma began as a proliferation of reticulum cells, which were the root-cells of the haemopoietic tissues. She thought that differentiation of some of the reticulum cells to haemic cells occurred, as shown by the finding of myeloid cells in lymphadenomatous lesions. The leukaemias, on the other hand, were characterized by proliferation of cells which were the more-differentiated progeny of reticulum cells, and which were already determined to leucopoiesis before the proliferative process started. Pullinger's views are supported by the occasional association of lymphadenoma and leukaemia.

It appears reasonable to adopt the suggestion that lymphadenoma and leukaemia are members of a larger group of closely related diseases—the reticuloses. This serves to emphasize the close relationship between the cell-types which characterize the two diseases, though it does not imply that the stimuli which initiate lymphadenoma and leukaemia are necessarily identical.

Summary

A case of lymphadenoma confirmed by biopsy is described. There was a good response to *x*-ray therapy, and no abnormality was found in the blood.

After two years of good health, maintained by careful irradiation, the clinical picture and blood findings of acute lymphoid leukaemia developed.

Other examples are quoted in which established cases of lymphadenoma have terminated with leukaemia or in which lymphadenoma and leukaemia have been present simultaneously.

The generic relationship between the two diseases is emphasized, in conformity with the view that both should be regarded as members of the group of reticuloses.

The evidence available does not suggest that the treatment of lymphadenoma by irradiation is responsible for a leukaemic termination in this disease.

We wish to express our thanks to Prof. L. J. Witts and Dr. A. H. T. Robb-Smith, who were kind enough to examine material from this case.

Medical Memoranda

Successful Treatment of Influenzal Meningitis with Sulphonamides

Pfeiffer bacillus meningitis is usually regarded as a fatal disease. The following report summarizes the case notes of a patient who recovered comparatively rapidly from influenzal meningitis with sulphonamide therapy.

CASE REPORT

A boy aged 5¼ years fell ill suddenly on May 30, 1942, with headache and vomiting. Next day his doctor, suspecting meningococcal meningitis, requested immediate admission to hospital. There was no history of any febrile attack among his family or immediate contacts prior to his illness.

On admission the patient's temperature was 101°, pulse 160, and respiration rate 22. He was conscious and intelligent, and complained only of headache. Physical examination revealed no abnormal findings apart from slight neck rigidity and a positive Kernig's sign. Lumbar puncture yielded a turbid cerebrospinal fluid, pale yellow in colour and under slightly increased pressure. The laboratory report was: protein, 165 mg./100 c.cm.; chlorides, 670 mg./100 c.cm.; sugar, absent. Cells, 387: neutrophils 64%, lymphocytes 30%, arachnoidal cells 6%. R.B.C.s, occasional. Culture showed *Haemophilus influenzae*.

Sulphapyridine 1.5 g. was given by mouth immediately, and was repeated after four hours; thereafter 0.5 g. was given 4-hourly. Because of the troublesome vomiting before admission nicotinic acid 50 mg. was given with each dose of sulphapyridine. The patient's general condition improved, vomiting ceased, and, apart from slight cyanosis, no new sign or symptom appeared. Lumbar puncture was repeated on June 5, when pressure was normal, and the laboratory report was: protein, 50 mg./100 c.cm; chlorides, 670 mg./100 c.cm.; sugar, diminished. Cells, 267: neutrophils 72%, lymphocytes 24%, arachnoidal cells 4%. Culture gave a slight growth of *H. influenzae*. On the same day the W.B.C. count was 10,000 per c.mm., 58% being neutrophils.

Unlike the typical course of meningococcal meningitis, the temperature took six days to settle to normal, but on June 9 it was judged safe to discontinue sulphapyridine when a total of 30 g. had been given. All signs of meningitis had gone, and the child's general condition was excellent. However, on June 11 it appeared that a recrudescence of infection had occurred. The temperature rose to 102°, and the pulse to 124; the child was irritable and photophobic, and had slight neck rigidity again. Lumbar puncture showed the C.S.F. to be under slightly increased pressure and just opalescent to the naked eye. Culture did not confirm our clinical diagnosis of a renewed meningeal infection. The laboratory report was: protein, 60 mg./100 c.cm.; chlorides, 670 mg./100 c.cm.; sugar, considerably diminished; culture, sterile. Cells 76: neutrophils 14%, lymphocytes 62%.

As soon as the recurrence of pyrexia was reported sulphathiazole was prescribed in large doses: 2 g. being given immediately and 1.5 g. 4-hourly thereafter, with nicotinic acid 50 mg. and mist. alk. 1/2 oz. The dose of sulphathiazole was reduced to 1 g. on the second day and 0.5 g. on the fourth day, and was discontinued on the seventh day at a total of 32 g. By this time the child was afebrile, bright, and normal in every way. Subsequent convalescence was rapid and without further setbacks. The patient was discharged home in excellent health on July 3.

There have been several reports published within the last twelve months of the sulphonamide treatment of Pfeiffer bacillus infections, with variable success. It would appear that a primary meningitis responds favourably to chemotherapy. Two important factors in the successful outcome of this particular case were undoubtedly the early institution of treatment and adequate dosage with the drug employed.

Reviews

BIOCHEMISTRY AND MORPHOGENESIS

Biochemistry and Morphogenesis. By Joseph Needham, F.R.S (Pp. 787; illustrated. 52s 6d.) Cambridge: The University Press. 1942.

Dr. Needham seems to have read all that has ever been written about embryonic development, normal and abnormal growth, tumours and grafts, regeneration of tissues, etc., and the influence on all of these of the internal and external chemical environment. Moreover, he is blessed with an amazing memory and a laudable desire to give to every worker his meed of credit. The result is a volume which is a mine of well-documented (in fact, too well documented) information in which it is sometimes difficult to see the wood for the trees. Nevertheless, the determined reader who tackles the 677 pages with the aid of the table of contents, the glossary, and the series of well-planned indexes will find a mass of information on any aspect of the subject of cell growth and differentiation which happens to interest him.

One of the best sections of the book, and one which will appeal to medical readers, is that which summarizes the work on the chemical nature of the "organizer." When the fertilized egg of the amphibian reaches the stage at which the uppermost layer of the cells of the blastula start to invaginate to form the gastrula, certain elongated cells appear on the dorsal lip of the blastopore. At the location of these cells there now develop the neural folds, which give rise to the neural tube, the forerunner of the spinal cord, and below them the notochord, the forerunner of the backbone. The axis of symmetry of the embryo is thus laid down and the position of the other organs as they develop is fixed in relation to this axis. By means of highly skilful microsurgery it has been shown that in normal development the stimulus to the morphological differentiation of the neural tube and notochord comes from these special cells at the tip of the blastopore. By excising these cells and grafting them into another blastula, invagination and the laying down of the embryonic axis can be made to take place at any position on the surface, and by inserting two or sometimes three grafts into the same gastrula the same number of embryonic axes can be made to develop. The discovery was later made that the organizer cells can induce growth even if killed by boiling, though the development induced is chaotic, and that extracts of dead cells from adult organisms can induce the same effect. Moreover, extracts from the tissues of one species can induce differentiation in the embryo of another. The growth stimulant (the evocator) is therefore a chemical substance; it appears to be a sterol and closely related in chemical structure and properties to the male and female hormones and to the carcinogens. It is present not only in the embryo but throughout all the tissues of the adult body, though normally maintained by some means in an inactive form.

The idea that normal differentiation (as distinct from mere cell proliferation) is also based on the presence of certain definite chemical substances and that these are located in definite regions in the egg cell is borne out by Swedish work on the developing egg of the sea-urchin. In this work it is shown that definite localities in the egg pass to definite cells in the early cleavage stages and that, up to the 16-cell stage, the cells of one or more embryos can be separated and re-combined in a number of permutations and combinations. Provided that the different zones of the original egg are present in a certain ratio in the reconstituted embryo a normal development will follow in spite of the drastic microsurgical history of the embryo. If, however, an abnormal quantity of any one zone is present (or if the zone is missing) abnormal development follows. Dr. Needham develops the thesis that normal growth and differentiation depend on the action of a stimulus (a definite chemical substance) acting on a tissue which is in the correct condition to receive it. The stimulus acting on a tissue not in the correct condition will lead to disordered growth, resulting in the formation of pathological abnormalities, among which teratomata are listed. In considering growth and development, the important influence of the genes—which certainly has a chemical basis—is not overlooked, certain pathological conditions, such as the absence of the brain in the fully developed foetus, being due to the presence of a particular gene.

Dr. Needham's book has been beautifully produced, the printing and the production of the plates being of the high standard associated with the Cambridge University Press. Perhaps it is ungracious to suggest that it is far too long. The subject is fascinating, and a book written in a more rigorously selective fashion would have commanded a large number of readers who would have read it for the story it has to tell. As it is, it seems likely to be used by a much smaller group of workers as a book of reference. But perhaps that is what Dr. Needham meant it to be.

LEGAL MEDICINE IN SOUTH AFRICA

Medical Jurisprudence: A South African Handbook. By W. F. Rhodes, M.B., Ch.B., D.P.H., I. Gordon, M.B., Ch.B., and Major R. Turner, S.A.M.C. With a foreword by the Hon. Mr. Justice H. S. van Zijl (Pp. 218; illustrated. No price given.) Capetown: Stewart Printing Company, Ltd.

Although a great deal of medico-legal practice is common to all countries, yet every country needs its own textbooks to deal with local peculiarities of law, physical conditions, weapons, poisons, and so forth. This book is the work of three members of the pathological staff of the Union Health Department in Capetown, teachers of medical jurisprudence in the University. Dr. Rhodes is senior pathologist and professor of medical jurisprudence. As Mr. Justice H. S. van Zijl says in his foreword, this is a book for medical practitioners and students who wish for practical guidance in their problems. It is not intended to be exhaustive, but none the less covers a very wide field. The study of skeletal remains, the early signs of death and appearances after death, are dealt with concisely but thoroughly. An interesting table from Drennan (1937) compares the characteristics of the European, Bantu, and Bush types. The mechanism of death is described, deaths of medico-legal importance are classified, and separate chapters are given to death by suffocation and drowning, and acute poisoning by carbon monoxide, hydrocyanic acid and its compounds. Sudden and rapid deaths due to natural causes are dealt with together—a better arrangement than splitting throughout the book the differential diagnosis from unnatural death. The chapter on anaesthetic deaths contains useful advice to anaesthetists and surgeons about their legal duties. British anaesthetists will be interested to note that the troublesome question which deaths associated with operations should be reported to the coroner is governed by statute in South Africa; but the decision whether the anaesthetic has contributed to the death seems left to the practitioners concerned. Poisons are not dealt with at any great length, and indeed a long section on them is practically useless to a general practitioner.

An outstanding feature of the book is the close attention which the authors have paid to all the aspects of the law governing their subjects. It is dealt with adequately in the appropriate places, and a late chapter contains extracts from statutes to which the reader is likely to have to refer. Some useful forms are added. The photographs are grouped at the end and include some revolting but valuable studies of persons who have died from various sorts of violence, and some interesting comparison pictures of bullets and cartridge-cases.

AVIATION MEDICINE

Aviation Medicine. By Ernst Jokl, M.D. (Pp 213. 10s 6d) Unie-Volkspers Beperk, Capetown. 1942.

This book contains a sketchy, anecdotal collection of published material dealing with high altitude, acceleration and of course deceleration, blind flying, and parachute jumping. Dr. Jokl's apology for the book is that "to my knowledge no textbook exists which presents the subject of aviation medicine in the light of the entire available evidence." This observation is fortunately true, since the knowledge of the physiology and pathology of flight is advancing so rapidly that a textbook is inevitably out of date, but Dr. Jokl's book does not in any way remedy the situation. There has been no attempt to select material critically, nor has the author used any restraint in wandering from the point to introduce sections under such headings as "Russia Can Fight" and "German Defeats." The text is copiously illustrated. There is no index and, although the book is intended to review modern work, no bibliography. Much of the reproduced material has historical interest, and the volume makes entertaining reading. It does not compete with existing textbooks of the same title, and it cannot be recommended as a serious guide for practitioners of aviation medicine who have access, through Service departments, to a wealth of knowledge which has accumulated in the past four years, but which will not be available for publication until after the war. This in itself would restrain the more conservative and well informed from attempting such a review at present.

Notes on Books

The revised fourth edition of the pamphlet *Physical Exercises for Asthma*, approved by the honorary Medical Advisory Committee of the Asthma Research Council, has been published by H. K. Lewis and Co. at the price of 1s. A feature of this useful publication is the wealth of excellent photographs showing how the exercises should be done.

The 84th issue of the *British Journal Photographic Almanac* has just been published by Henry Greenwood and Co., 24, Wellington Street, Strand, W.C.2. It is edited by Mr. Arthur J. Dalladay, and contains 392 pages, including a 32-page pictorial supplement of photogravure reproductions of works by well-known photographers It can be obtained from the publishers at 3s. 6d. (paper covers) and 5s. (cloth bound).

Preparations and Appliances

A SUBSTITUTE FOR THE FLOWMETER IN OXYGEN THERAPY

Lieut. MARTIN WRIGHT, R.A.M.C., and Prof. RONALD V. CHRISTIE, St. Bartholomew's Hospital, write:

A special Y-tube has been designed to enable two patients to be supplied with oxygen from one cylinder with certainty that each is receiving practically the same amount. If the rate of flow of oxygen to one of the patients is measured by means of a flowmeter, it can be assumed that the amount received by the other is nearly the same. This halves not only the number of flowmeters required, but also the number of pressure-regulating valves, which are even more expensive and difficult to obtain and quite impossible to improvise. This consideration is only likely to be of importance if poison gas is used in this country, when the demand for oxygen therapy may be great and the equipment required may exceed that at present available.

The Y-tube is an ordinary metal one of standard pattern, and in each upper arm is inserted a brass disk about 1/10 in. thick, and having a central circular orifice exactly 1/32 in. in diameter. These pinhole orifices provide a high resistance to the flow of oxygen, so that any resistance due to the method of administration or the length of connecting tubing is negligible compared with it. Using this Y-tube, two patients can be supplied with oxygen from one cylinder—one through a B.L.B. mask, which has negligible resistance, and the other through nasal tubes or a spectacle-frame mask, both of which have high and unpredictable resistances; and the flow to the two patients will not differ by more than 0.75 litre a minute at a flow of approximately 5 litres a minute to each patient. The pressure in the tube leading from the cylinder to the Y-tube will be about half of one atmosphere, but this is well within the capacity of any ordinary rubber tubing. The resistance produces a rather unpleasant hissing noise, but this is not likely to be a matter of importance in the circumstances under which the device is likely to be used. Another disadvantage is that, as two patients are being supplied from one cylinder, it may be necessary to check the rate of flow twice as often as with one patient, and if a pin-valve is used the rate of flow to each patient cannot exceed 5 litres a minute without producing irregularities in the flow due to freezing up of the valve. If a proper pressure regulator is used, however, these difficulties will not occur.

Instructions for Use.—(*a*) The lower limb of the Y-tube should be connected to the oxygen cylinder and the upper two limbs to the patients. (*b*) If a flowmeter is inserted between the Y-tube and one of the patients it can be assumed that the other patient is receiving practically the same amount of oxygen. (*c*) The rate of flow to each patient should not exceed 5 litres a minute unless a pressure-regulating valve is employed. (*d*) A pressure-regulating valve should be used, if available, for this reason, and also because otherwise the rate of flow will have to be checked frequently. (*e*) As the pressure within the tubing between the Y-tube and the cylinder is considerable the tubing may blow off; it should therefore be a good fit and be well pushed on to the stem of the Y-tube. (*f*) It is preferable that the same type of equipment for oxygen administration should be used with each patient, but it is not essential. (*g*) This Y-tube resistance should be employed only if a sufficient number of flowmeters are not available.

This Y-tube resistance is manufactured by the British Oxygen Company.

THE OUTBREAK OF SMALL-POX IN GLASGOW

SOME COMMENTS, A CRITICISM, AND A COMPARISON

BY

C. KILLICK MILLARD, M.D., D.Sc.

Ex-M.O.H. for Leicester

The outbreak of small-pox in Glasgow last summer, a report on which has been published in the *Journal* (1942, **2,** 627), was an exceptionally interesting one and calls for some comment. First, I would draw attention to the following points:

1. The outbreak probably would never have occurred but for the unfortunate mistake in diagnosing the first case—the electrical engineer on board the ship from Bombay—as one of measles. It is often difficult to distinguish the eruption of confluent small-pox (as this case was) from measles at the outset, while it is still in the papular stage, but after 48 hours, when the eruption becomes vesicular, there is usually no real difficulty. In this instance the diagnosis of small-pox was not made until after the arrival of the vessel at Glasgow on May 29, five days from the first appearance of the eruption.

2. The great majority of the ship's crew of over 200 had been recently vaccinated (in 1940). Not one of these contracted the disease. But of 37 members of the crew who had never been vaccinated, seven contracted the disease and one of them died. This is fairly conclusive evidence of the value of recent vaccination, and of the desirability of all those sailing to or from the East—the home of small-pox—being protected by it.

3. On the other hand, of two passengers who contracted the disease, one was a Polish officer aged 23, who had been vaccinated in infancy and again at the ages of 7 and 14—evidence that even three vaccinations, if not recent, are insufficient to protect from attack.

4. One of the "ship" group of cases was a boarding medical officer, aged 34, vaccinated in infancy but not since. It seems surprising that a medical man, specially appointed to board ships, and presumably for the purpose of looking out for cases of small-pox, should neglect to take the elementary precaution of adequately protecting himself by recent vaccination.

5. Not one secondary case of small-pox (apart from the "city" group) resulted from the 10 cases in the "ship" group which were infected from the original case—striking testimony to the efficacy of modern routine measures.

The "City" Group of Cases

There were 25 cases in this group, of which 21 were primary. Of the latter, all except the last three occurred in a close bunch in the space of 16 days. Allowing for variations in the incubation period, it is possible, the report suggests, that they were all infected in the short space of 10 days—June 9 to 19. This is a point of some importance, as I shall show later. It clearly points to a common infecting cause of strictly limited duration. When that cause, whatever it was, ceased to be operative the outbreak collapsed.

A remarkable feature of the "city" group was that in not one of the 21 primary cases was any clue discovered as to the source of infection. Their occurrence within a month of the arrival of the ship points, of course, to there having been some connexion with the ship cases; but, whatever its nature, it was not discovered. The authors of the report suggest that it was either (1) a "missed" case which left no trace behind, or (2) aerial convection from the small-pox hospital. They are inclined to favour the former because of the distance from the hospital. The four secondary cases in the "city" group were all direct contacts, and the fact that there were only four and that these gave rise to no further cases again indicates the remarkable success of modern preventive measures.

It is interesting to note that of the 25 cases in the "city" group, eight had never been vaccinated, 13 had been once vaccinated, three had been twice vaccinated, and one (a woman aged 49) had been vaccinated three times (1, 17, and 27 years). As is almost always the case, those patients who had never been vaccinated suffered more severe attacks than those who had.

The Mass Vaccination Campaign

We now come to a debatable and very important practical question, the mass vaccination campaign: Was it really necessary, and what effect did it have in controlling the outbreak? It is no light matter to inflict vaccination and all that it entails upon 500,000 persons—men, women, and children. The report states fairly the grounds which led the authorities to decide on June 28 (four weeks after the arrival of the ship) in favour of the step. The determining factor was, of course, the occurrence of the "city" cases. On the date in question there had been nine such cases in the last four days, scattered over different parts of the city, and with no clue as to the source of infection. A war was on, and it was thought that this might make routine measures less effective. Also, a widespread epidemic would seriously affect war production. The history of past outbreaks had to be taken into consideration too. It is easy to be wise after the event, and nobody could then foresee that the outbreak was going to collapse so suddenly. On the basis of accepted theories and teaching about small-pox and vaccination, very many people will undoubtedly acclaim the decision as a wise and proper one—including, of course, all those who think "the more vaccination the better." All the same, there had been only 15 cases altogether in the "city" group up to the date in question.

This much can certainly be said: a vaccination campaign on such a great scale, involving the rapid opening of 25 emergency vaccination stations in various parts of the city, the provision of the necessary staff, medical and lay, the arrangements with general practitioners for private vaccinations, the obtaining from the Government of the very large amount of calf lymph required, together with all the publicity and propaganda necessary to secure the co-operation of the public and to induce them to come forward and submit to vaccination, was a great administrative effort, calling for much energy and ability in its successful execution. It must have entailed a vast amount of hard work upon the staff of the Glasgow Health Department, under the leadership of their distinguished M.O.H., Sir Alexander Macgregor.

It is only natural, human nature being what it is, that, having made this great effort, much if not most of the credit for the sudden termination of the outbreak should be attributed by many people to what was undoubtedly the most outstanding and spectacular—as well as the most expensive—of the measures taken to control the outbreak. Thus the authors of the report, after explaining the considerations which led to the decision to initiate the campaign, and after referring to previous outbreaks which had lingered on for many months, say: "The present experience is in strong contrast; and it may be said that the people themselves, by taking timely advantage of the advice given and the facilities provided, stopped the outbreak at its start." And Sir Leonard Rogers, in an address entitled "The Efficacy of Vaccination against Small-pox" (*Medical Officer*, Dec. 5, 1942), reprints of which are being issued free by the Research Defence Society for distribution to members of local health authorities, says: "The remarkable accomplishment of the Glasgow health authorities in vaccinating 500,000, nearly half the total population, saved the situation for the time."

I hope that it will not seem grudging or ungracious on the part of one who has himself spent the greater part of his professional life in administrative public health work if I express a doubt as to whether all this mass vaccination had anything whatever to do with the sudden termination of the outbreak. Was it really a case of "cause and effect"? Was it *post hoc* or *propter hoc*? Would not the "routine" measures (as the report calls them)—i.e., the prompt isolation of every case as it occurred, the surveillance and vaccination of contacts, together with other incidental precautions—have been just as efficacious without all the great effort of the vaccination campaign?

The issue is of much practical importance because the example of a great city like Glasgow is likely to be followed by other local authorities faced with outbreaks of small-pox; and especially so if it is believed that it was the mass vaccination campaign which really saved the situation. Moreover, since any outbreak of small-pox, once it gets a firm foothold, is a danger to the entire country, the issue raises the whole question of our national policy in regard to vaccination. Therefore the issue must be faced, and no personal considerations must stand in the way of free discussion.

The first point, then, which I wish to make is that although such a large number of persons were vaccinated in the Glasgow vaccination drive it only amounted to about half the total population; so that there were still some half-million persons who did not get vaccinated, and only a very small minority of these would be protected by recent vaccination already performed. Therefore there was an ample supply of susceptible material left for the infection to spread amongst, had it not been under control, and had the circumstances been otherwise favourable. But the chief argument against the campaign having had anything to do with the cutting short of the outbreak is to be found in a comparison of dates. If we refer to Table II in the report, which gives the date of eruption in each case, and if we allow 14 days for the incubation period, we shall find—excluding the last three cases of the outbreak (i.e., the case at the mental hospital, the contact case arising from it, and the patient who sickened in London)—that there was no case infected later than June 26 in the whole outbreak. But the decision to start the vaccination campaign was only taken on June 28, two days later. It is true that seven cases (three of these being contacts, and therefore under surveillance, and one the London case) developed the disease after June 28, but they were all infected before that date. It seems quite evident that the infecting cause, whatever it was, which led to the infection of the bunch of primary "city" cases during the 10 critical days, June 9 to 19, had ceased to be operative before the decision to start the campaign was taken. In other words, *the outbreak was virtually over before the vaccination campaign was started.* This is not intended as a criticism of the decision to launch the campaign, because, as we have already said, it was not possible on the date in question to foresee what was going to happen; but it *is* a criticism of the claim that it was the vaccination campaign which brought the outbreak so quickly to an end. I submit with confidence that the indications all point the other way. I suggest that if only the authorities had waited another week or two they would never have embarked on the campaign at all.

Experience of Other Towns

In order to view the Glasgow experience in proper perspective it is desirable to compare it with that of other towns where outbreaks of small-pox have occurred but where recourse was not had to mass vaccination; and I will take the case of Leicester, of which I can speak from personal experience.

In the year 1902, when there was a good deal of major small-pox in the country, the disease was introduced into Leicester on eight occasions. The first seven importations were successfully controlled, and only nine secondary cases resulted, making 16 cases in all. The type of disease was severe, and five of them proved fatal. Then at the end of the year a tramp, vaccinated in infancy, walked to Leicester and was admitted to the workhouse. He began to sicken the following day with a mild modified attack, which unfortunately was diagnosed as chicken-pox. No precautions were taken, and for six days he was not isolated, living in fairly close contact with 60 other inmates. Under these circumstances it is not surprising that 20 further cases occurred in the institution before the outbreak was suppressed. It is quite possible that the infection leaked out into the town, for a small number of cases kept cropping up throughout the first quarter of 1903. And then came the remarkable outbreak which I wish to set against the recent one in Glasgow.

The Leicester Outbreak, April, 1903*

On April 15, without warning, as there had been practically no cases for a fortnight, 4 cases were reported in various parts of the town. These were followed by 2, 2, 5, and 5 on succeeding days, and then no fewer than 14 cases occurred in a single day. For the first four weeks the figures were 53, 21, 34, and 48. What made the outbreak especially disconcerting was that in scarcely any of the cases could the least clue be obtained as to the source of infection, and no common factor in any way connecting the cases could be discovered. Thus in the first 11 days, before secondary cases began to occur, there were 65 cases, 62 of which were untraced, and these were scattered over two-thirds of the town, in 61 houses in 58 streets. Of the patients 37 worked in 32 different factories or workplaces; and 14 school children were attending 11 different schools. Bearing in mind that for 16 years Leicester had openly revolted against vaccination, that all prosecutions for default had entirely ceased and the compulsory vaccination law was virtually a "dead letter," and that the amount of vaccination performed had been almost negligible,† it must be admitted that apparently the circumstances attending this outbreak were exceedingly favourable for a devastating epidemic. Undoubtedly many people thought that Leicester's hour had now come; and some even considered that it might not be altogether a bad thing if the town were taught a salutary lesson. But it was not to be. After the first four weeks the outbreak began rapidly to decline, the number of fresh cases each week falling from 48 to 22, 14, 10, 4, 2, 1, and a fortnight later none was reported. Even a well-vaccinated town could hardly have done much better. The total money cost of the outbreak was estimated at under £3,000.

The Cause of the Leicester Outburst

The only two possible explanations, as at Glasgow, seemed to be: (1) "missed" cases, of which absolutely no trace was discoverable; and (2) aerial convection from the small-pox hospital. When the outburst began 20 convalescent cases were under treatment and the prevailing winds were favourable; but there was no special incidence on the side of the town nearest to the hospital. Also, the distance of the hospital—a mile from the outskirts—seemed against the convection hypothesis; but on the whole it seems the most probable explanation. But whatever the cause, it ceased to operate—as was the case at Glasgow—and then ordinary routine measures were effective in preventing further spread. Fortunately the death roll was very much smaller than might have been expected, and the unvaccinated child population escaped much more lightly than was feared would be the case. There was only slight evidence of "picking out" the unvaccinated.

The Measures Adopted: No Vaccination Campaign

The measures taken to deal with the outbreak were the routine ones now universally adopted. As M.O.H. I personally visited every case, confirmed the diagnosis, arranged for immediate removal to hospital, and used my best persuasive powers to induce other inmates of the household to get vaccinated at once. Usually I vaccinated them myself on the spot. No appeal was made to the general public to get vaccinated, and there was an entire absence of alarmist posters urging vaccination. The local press co-operated by not "writing up" the outbreak and by avoiding sensational headlines; consequently, business went on as usual and there was little interference with the trade of the town. Where it was thought desirable that contacts should not return to work, compensation was paid to them for loss of wages. One thing I think may safely be said: if Leicester had gone in for a vaccination campaign it would certainly have been hailed by many as a triumph for vaccination and would have been given the credit of having saved the town from a great disaster.

Just one thing remains to be added. While I think that the Glasgow vaccination campaign was unnecessary, I can imagine circumstances in which such a campaign would be called for—and that is, if a serious epidemic of major small-pox were really to get out of hand. Such an occasion happened at the town of Dewsbury in 1893 and again in 1894, and in the notorious Gloucester epidemic of 1895. At both these places there was a complete breakdown of the ordinary routine measures for dealing with small-pox; the local authorities were quite overpowered, and they were left to their fate by the old Local Government Board, so far as giving them any practical assistance was concerned. But this was half a century ago, and the likelihood of such a breakdown occurring to-day, with our so greatly improved health organization, both local and central, is comparatively small.

---

* The abbreviated account which is here given is taken from my book, *The Vaccination Question in the Light of Modern Experience*, H. K. Lewis Ltd.

† The number of unvaccinated children in the town at this time would be about 70,000.

HEALTH EDUCATION AND VENEREAL DISEASES

At a Conference held last week by the Central Council for Health Education to discuss the educational campaign against venereal diseases, Dr. CHARLES HILL, chairman of the Central Council, said there was general agreement that the problem could not be effectively tackled until the curtain of secrecy which surrounded it was lifted. It was not enough to disseminate facts about venereal diseases, but a method and policy of dealing with the problem must be formulated, and a frank discussion on that subject was the purpose of the Conference.

The MINISTER OF HEALTH (Mr. Ernest Brown), after welcoming the delegates, said that Defence Regulation 33B, which was deliberately limited in scope, left unchanged the general voluntary basis of treatment. It was intended, he said, to stop a gap in the voluntary system which had existed for some time but had assumed much greater seriousness during the war. The regulation was a necessary wartime measure in the interests of public health, but it was only one item in the Government's programme for checking the increase in venereal diseases, and did not in any way reduce the need for a widespread intensification of education.

The Primate's Opposition to 33B

The ARCHBISHOP OF CANTERBURY, who is president of the Central Council, began by making clear his personal position. Early last autumn when he accepted the invitation to become president he was aware that one of the most immediate concerns of the Council would be educational propaganda on this subject in which he hoped he could take some useful part. When Regulation 33B appeared he was greatly disquieted, and submitted to the Minister his resignation of the presidency, saying that he could not hold the office and keep silent, while at the same time it seemed unfair to him to use the position as a vantage ground for criticizing the regulation. But the Minister asked him to retain his office while being free to criticize.

Venereal disease, said Dr. Temple, was communicated almost—not quite—entirely in illicit sexual intercourse. If men and women would abstain from fornication the problem confronting the Minister of Health would be negligible. The minute residuum would be a purely medical problem. But the evil in its present bulk was a moral problem. The object first to be aimed at was the practice of continence. All that could be done by the promotion of a healthy family life, by the influence of school, and by the attitude of authorities should be done. It was a fundamental principle that Governments affected the conduct of citizens far more by the principles implicit in their acts than by the requirements of legislation or the severity of penalties. But in dealing with venereal diseases the Government had systematically ignored this principle. Thus, in the Army instruction was given to recruits in the use of prophylactics, the implication being that the authorities expected a considerable number to practise fornication. He believed that this method by its inevitable suggestion caused an increase of promiscuous intercourse and therefore of the disease which it was designed to prevent. The moral problem was treated as if it were primarily a medical problem. His fundamental objection to 33B was on the same ground. Its existence tended to create the suggestion that infectious contacts were being dealt with, and that the concern of the Government was to make fornication medically safe. But to make venereal diseases compulsorily notifiable would be far worse than the regulation. It would lead to concealment of symptoms and would reduce the numbers seeking early treatment. His Grace mentioned seven points which he thought should be stressed in any instruction in the subject, the first being the sacredness of sex and the second the duty and possibility of chastity.

In the general discussion several speakers, medical and lay, challenged the Archbishop's point of view. Bailie VIOLET ROBERTON, a member of Glasgow Corporation, who spoke on the problems of a large port, said that she had been charged to say to the Minister that in her city they welcomed unreservedly his new measures; they congratulated him on the courage with which he had tackled this problem, and while they knew there were difficulties in administration, they felt that a definite step forward had been taken.

A Recantation

The first medical speaker, Dr. OTTO MAY, supported the Archbishop. He agreed that the medical part of the problem was subsidiary. If there was no promiscuity there would be no venereal disease. One of the "ten points" in the advertisement campaign declared that abstinence from sex irregularity was never harmful. It was a difficult topic, but personally he thought there was a great deal of exaggeration in the talk about a primitive urge. Mankind had learned to discipline a good many of its primitive urges in the course of evolution. One important point was the disharmony between the age of sexual maturity and that of economic maturity; the Beveridge plan would make early marriage more easy. But however much the importance of total abstinence from extramarital intercourse was taught it was useless so long as every possible incentive to the opposite was left to tempt young people, especially street prostitution. It might be that in some cases abstinence was a cause of neuroses and repressions, but it was necessary to educate for the majority, not for the medical exceptions. These cases might be tackled in the consulting room, but should not be talked about on the platform. Dr. May added that twenty years ago he wrote a book on prevention of venereal diseases in which he advocated the teaching of personal prophylaxis as an essential part of the campaign, but he was older now and had come to the conclusion that the advocacy of prophylaxis implied a sanction for misconduct which would be much more powerful than its deterrent effect.

Dr. MAITLAND RADFORD (M.O.H., St. Pancras) said that the difference between the secular and the religious approach did not constitute a barrier; the two different points of view supplemented each other. With great respect, he thought that a false antithesis had been put before the Conference. His Grace had said that it should be part of the educational campaign to teach the sacredness of sex, but it was untrue to represent it as a fact that sex was universally regarded as being sacred. The secular approach to sex allowed a wider latitude in sex behaviour than did the religious approach, and it did not seek to impose a uniform pattern. He was sure, however, that those who upheld the different viewpoints could work together. The differences between them were there and should be stated, but there was a common working platform. Whatever the formula accepted, irresponsible sexual behaviour was to be deplored.

Various Methods of Educational Approach

It would give a wrong impression to suggest that the Conference was wholly occupied with this controversy. Many excellent contributions were made on different educational aspects. Miss MANCHEE, chief almoner at St. Mary's Hospital, spoke of the need for the social worker at the V.D. clinic. Doctor, nurse, and social worker, she said, made the ideal triple partnership. If a clinic was too small to engage the whole of an almoner's services they should be shared with some other department of the hospital. Lord WINSTER spoke on work among seamen. The ports, he said, represented perhaps the main problem. The majority of cases occurred among foreign seamen. He regarded it as one of the good things which had come out of this war that the harmful and unhealthy atmosphere of fear, mystery, and hypocrisy which had prevailed too long in regard to these diseases was being dispelled. Dr. O. HAMILTON WILKIE, director of V.D. services, Leicester, described the scheme in operation in his city and county, in particular an extensive education campaign during which he had given 180 lectures. Dr. T. O. GARLAND complained that many pamphlets on health education, while they mentioned venereal diseases, did not mention the symptoms by which they could be recognized, and in none he had read was any information given on prophylaxis. There was some queer intellectual kink which made it appear right to teach people how to be treated, but wrong to teach people how immediately to disinfect themselves.

At the end of each of the two sessions many joined in a general discussion, but no resolutions were put, the Conference being for the exchange of opinions and experience.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY MARCH 6 1943

PARLIAMENT AND THE BEVERIDGE REPORT

Now that both Houses of Parliament have discussed the Beveridge report and the Government has explained its attitude to it, we may examine the situation in relation to the recommendation of the Council of the B.M.A. to the Representative Body. It will be recalled that the Council recommended that the Association should be willing to co-operate in the preparation of a scheme for comprehensive health and rehabilitation services available to all members of the community, provided three conditions were fulfilled. The first condition was that the Government should accept the assumptions of the report and should put into operation the proposals of the report taken as a whole. The focus of criticism of the Government's statement is on the fact that it has not decided immediately to act upon Sir William Beveridge's proposal that there should be a Ministry of Social Security. The failure to do this, or at least to appoint a Minister of Social Security, has been criticized by members of all political parties and has led to the general impression that the Government is planning to avoid action on the report as a whole. This is relevant to the attitude the profession will adopt to the proposals for a health service. In his exposition of the attitude of the Government, Sir John Anderson stated that it agreed that the administration of the insurance side of the entire social security scheme should be consolidated into one organization. It was a question whether such a unified organization should be a new Ministry or some kind of statutory board. Whatever it was, it would be set up as soon as legislation introducing the new scheme had been passed in Parliament. In the meantime it might be desirable, Sir John continued, to create the nucleus of the new organization now, to work with the Departments concerned in bringing the project as a whole into legislative form. This nucleus staff would be responsible to the Minister without Portfolio (described by Viscount Samuel in the Lords debate as "the Minister with Pigeon Holes," and by Archbishop Lord Lang as "becoming a sort of Mother Hubbard"). The general lines of development of the social insurances in the Beveridge report were those which the Government would wish to follow, and in considering its future financial commitments the Government's attitude was: "Let us not be deterred by doubt as to finance from putting our plans into shape." It cannot be denied, however, that Sir Kingsley Wood's speech implied that there were doubts in the Government's mind as to its financial ability to put plans into action. The Government, according to Sir John, had looked at the scheme as a single, coherent plan of social insurance, and the various parts of it quite clearly hinged together. The Government, too, accepted Sir William's three assumptions. On the evidence before them the Representative Body will have to determine whether the Government has decided "to accept the assumptions of the report and to put into operation the proposals of the report, taken as a whole."

Before referring to the other two provisos laid down by the Council, we may review briefly what appears to be the Government's attitude to Sir William's Assumption B. In the House of Lords the Lord Chancellor made the following statement: "The Government had every intention of carrying out the comprehensive health service." This, Sir John Anderson observed, implied the reorganization of the existing services—National Health Insurance, the general and specialist health services of local authorities, major hospital and institutional services, and so on. By "comprehensive" he meant first a service covering the people as a whole and, secondly, the inclusion of institutional treatment. The object was to secure, through a public, organized, and regulated service, that every man, woman, and child who wanted it could obtain the whole range of medical advice and attention. The fullest use was to be made of existing resources, and the idea of the new service must be one of co-operation of public authorities, voluntary hospitals and other voluntary agencies, and the profession towards one common end. There must be no doctrinaire scrapping of good existing resources, nor must there be overlapping. The responsibility for seeing that in any area the service was full and efficient must be on one ultimately responsible to public authorities. Experience justified putting this ultimate responsibility on to local government machinery. Perhaps it was most important of all, he said, to maintain to the greatest possible extent the principles of free choice of doctor and of the family-doctor relationship as the background of general medical practice. There should be the least possible disturbance of existing relationships between doctor and patient. In the view of the Government this need not be inconsistent with the principles of group public practice at well-equipped clinical centres. The third proviso of the Council—namely, that those who wanted to could make private arrangements for medical treatment—is satisfied by the unequivocal statement that the Government has no intention whatever of forcing the new services on those who wish to make private arrangements. The Lord Chancellor said: "As we conceive the scheme it is not a scheme that will automatically bring to an end a medical man's private practice, and, as we conceive it, it is not a scheme in which the voluntary hospitals will have nothing to do." In the same way both Sir John Anderson and Mr. Herbert Morrison made it clear that there was no intention on the part of the Government to "destroy the institution of voluntary hospitals."

The most important of the Council's conditions for co-operation was "that the character, terms, and conditions of the medical service are determined by negotiation and agreement with the medical profession." The details of the new scheme, Sir John Anderson said, would be worked out by the health departments with the help of other main organizations, local authority, voluntary, or professional, on whose active participation the success of any new organization must depend. The Ministry of Health has already been conducting discussions with the British Hospitals Association, and it has just asked the B.M.A. to lead a deputation representing the various branches of medical interest, for preliminary discussions, on March 9. There would, therefore, seem to be little ground for the suspicion on the part of some of our correspondents that a Machiavellian plot is being hatched by a Government which intends to keep the medical profession ignorant of its intentions until the last moment. So long as there are representation of the different interests involved, full freedom of discussion, and give-and-take in negotiation, we hope that those doctors who must perforce remain onlookers will give their wholehearted support to the various medical men and bodies who are determined to see that professional interests are maintained and promoted so long as they do not hinder the provision to the public of all those facilities that make for the promotion of health, the prevention of disease, and the care of illness. It should be understood that neither the B.M.A. deputation nor any other professional group has any power to commit the medical profession to any form of service. The results of all discussions will be referred back for decision to appointing bodies—for example, in the case of the B.M.A. this includes consideration by the Divisions and decision by the Representative Body. In the House of Lords Lord Dawson voiced the feelings of most medical men when he said that it was not to be expected that the medical profession would be moved about and take its orders from the laity. Under the authority of Parliament the profession would wish for self-determination, and this it will seek.

SPLENOPATHIC LEUCOPENIA

In a recent publication Wiseman and Doan[1] describe a syndrome which they call primary splenic neutropenia, and record five cases of their own and two others from the literature which they believe to be the only published cases of this disorder. The features common to all seven cases were severe leucopenia, splenomegaly, and an over-active bone marrow. In each case there was complete relief of symptoms after splenectomy, and the number of circulating granulocytes immediately returned to normal. This happened in spite of the fact that there had been no response to liver therapy, pentnucleotide, and blood transfusions. The authors compare the disease with congenital haemolytic anaemia and essential thrombocytopenic purpura, and believe that all three conditions are caused by an abnormality of the reticulo-endothelial cells in the spleen, which is responsible in this syndrome for an excessive destruction of the granular leucocytes. They find support for this theory in the appearance of the splenic pulp after operation, scrapings of which, stained supravitally, showed a large number of phagocytic clasmatocytes containing neutrophils and occasional red blood cells and normoblasts. They also state that the marrow showed a specific myeloid hyperplasia, but it is not easy to be convinced of this from the cell counts given with the case reports. The marrow was described as being unusually cellular, but there was a wide range in the ratio of myeloid to erythroblast cells in the different cases. The findings certainly offer a contrast to the maturation arrest of the leucocytes in toxic agranulocytosis, but they do not differ materially from the changes observed in many haemolytic disorders.

The authors recognize that in their patients the granulopenia was always accompanied by some degree of thrombocytopenia and haemolysis, and a detailed examination of the case reports shows that in each of the five there were a fall in the number of platelets and evidence of considerable red cell destruction with a corresponding increase in erythropoiesis, normocytic anaemia, reticulocytosis; and raised icteric index. It is difficult to see why it was necessary to include a case of thrombocytopenic purpura in a new disease group. True there was a moderate leucopenia (3,400 to 5,100 per c.mm.), but this is known to occur in some cases of essential thrombocytopenia, and in every other respect, including age and sex, the symptoms were typical of this disease. Even the bone marrow showed a myeloid : erythroblast ratio of only 1 : 5. The authors say that in their experience the spleen in uncomplicated thrombocytopenic purpura is never enlarged, either clinically or at operation, but this is not the experience of most haematologists.

Although Wiseman and Doan are at some pains to stress the recent recognition of this syndrome, it is only fair to point out that the conception has been familiar to European haematologists ever since Frank's[2] classical article on aleukia in 1925, and such cases have been successfully treated by splenectomy. Their infrequent occurrence sufficiently explains the absence of published accounts. Frank called the condition "splenopathic leucopenia," for he believed that the spleen was responsible for an excessive destruction of the circulating leucocytes and that the changes in the bone marrow were secondary. He suggested that in all probability this was merely an exaggeration of one of the normal functions of the spleen. He recognized the value of splenectomy, and observed the close relation of the syndrome to essential thrombocytopenia and other diseases in which splenomegaly is accompanied by leucopenia. In particular he cited the leucopenia found in kala-azar, chronic malaria, typhoid fever, in the spleno-mesenteric type of Hodgkin's disease, and in Banti's disease. While clearly aware of the difference in the primary noxious agents, he believed that the resultant granulopenia was due to a specific effect of the splenomegaly, which was similar, if not identical, in the separate diseases, and which could occur in cases where there was no recognizable aetiological cause. He stated that it was possible that splenopathic leucopenia was really a terminal state of a series of transitional phases. The other circulating blood cells were also affected, and in certain instances the abnormal destruction of the platelets might exceed the leucopenia. This conception of the splenic origin of leucopenia is very similar to the one reached by Wiseman and Doan, but it brings out the point that common conditions should be excluded before diagnosing such a rarity as primary splenic neutropenia. Splenomegaly and leucopenia are often the initial symptoms of leukaemia and the progressive hyperplasias of the reticulo-endothelial tissues, and it is advisable to make careful investigation and to observe the natural history of the illness before deciding that the symptoms will be relieved by splenectomy.

INFECTIOUS POLYNEURITIS

During and immediately after the last war 18 cases of polyneuritis, recurring endemically, were described under various titles by British, French, and American authors.[3 4 5] In this country it was known as acute infectious polyneuritis and was chiefly sporadic, although often several cases occurred at the same time in a comparatively small district. In France, Guillain and Barré[6] found that in all cases the cerebrospinal fluid showed high protein in association with a low cell count, and the name Guillain-Barré syndrome has therefore been generally adopted in that country. Most of the recent literature has come from the United States, and in a review of the subject Roseman and Aring[7] have added 16 fresh cases, in 3 of which post-mortem studies were made.

The clinical symptoms are characteristic enough. The disease, which is most often seen in the higher age groups, appears to follow a mild influenza-like infection, usually at an interval of one to three weeks. The most striking initial symptom is pain in the back and legs, often with numbness and tingling. Paralysis of a lower motor neurone type, with a varying amount of anaesthesia of the glove-and-stocking type, sets in more gradually or follows the subjective symptoms at an interval of some days. Contrary to the general opinion, the facial nerves are involved in the majority of cases, and all the other cranial nerves may also be involved. Paralysis of accommodation and of the palatal muscles may make it difficult to distinguish the condition from diphtheritic paralysis, but the cranial nerves are usually affected after the lower limbs. The rectal and vesical sphincters are generally spared. Pyrexia is infrequent, but the pulse rate is often increased. It is the experience of American as well as of English physicians that artificial respiration rarely saves life; death occurs from respiratory paralysis in from 14 to 40% of cases. The increase in protein in the cerebrospinal fluid, though considered by Guillain and Barré as a point of major diagnostic value, has not been constant, especially in the initial stages of the disease. It is, however, of value later, and has been found to persist for many months, and even up to 5 years in some cases. No treatment for the disease is known, and bacteriological and experimental studies have shed no light on its causation.

The pathology of the disease, as described by Roseman and Aring, is not limited to the nervous system, although that has been most studied. The changes are most evident in the peripheral nervous system, both somatic and sympathetic, and include oedema of nerve roots and trunks, with foci of phagocytic cells and rarer lymphocytes, hyperplastic changes in the sheath of Schwann, irregular swellings and corkscrew formations on the axis cylinders, and degeneration of myelin sheaths. The dorsal and sympathetic ganglia show some degeneration with phagocytosis of some nerve cells, oedema of the ganglia, and increase in interstitial cells. Chromatolysis of cells in the anterior horns and the cranial nerve nuclei and minor changes in the nerve cells of the cerebrum and cerebellum are also seen. In the hearts of two fatal cases there was diffuse interstitial infiltration with polymorphonuclear and mononuclear cells; in one case necrosis of scattered muscle fibres had occurred, and in the other there was also local inflammatory infiltration of the wall of a coronary vessel and focal phlebitis of a pulmonary vein. In all three cases on which post-mortem examinations were carried out there were focal necrosis of liver cells with cellular infiltration as well as portal infiltration, and degeneration of the suprarenal cortex with accumulation of mononuclear cells. The authors point out that a pantropic virus would not be expected to produce these changes. In a more recent fatal case in a child of 4 years Aring and Sabin[8] found similar changes in the spinal cord and nerve roots. Animal experiments with the material from this case were also negative.

Though these studies do not point to any definite aetiology they show acute infectious polyneuritis to be a general disease and not merely one of the peripheral nerves.

STANDARDIZATION IN COMMUNAL FEEDING

While the Minister of Labour is dealing with wages and conditions of employment in the catering trade he might well have gone further, perhaps in association with his colleague Lord Woolton, and have set up some central body to prescribe standards of food values and of hygiene and cleanliness in the preparation and service of food to be observed by all catering concerns, whether in public or private hands. The matter is becoming more important because of the large numbers of people who now have their principal meals away from home, either on account of the necessities of their employment or education or to relieve domestic difficulties. Rationing and limitation of choice, lessened palatability of foods, and narrower margins of nutritional values render all the more important some central supervision of the quality and the preparation of food. Certain standards of cleanliness and care in the kitchen and service staff should also be exacted.

It is quite possible that community feeding, having proved its convenience and economy, may persist and develop in this country after the war. Some will object that this will mean the further disintegration of the family unit, but it is a hard saying that to compel the housewife to steamy and greasy culinary employment for several hours of every day is a means of safeguarding the family; it may easily have had the opposite effect. If the social meal has come to stay, the experience in Soviet Russia, where communal feeding has been tried out on a large scale, may be worth studying, while making allowances for the different national economy and way of life. Some interesting and (so far as possible) up-to-date information on this subject has been collected by F. Le Gros Clark and circulated as a brochure under the title *Soviet Forms in Communal Feeding*.[1]

In Soviet Russia collective feeding is part of a State-directed policy. It is considered that centralized food depots are likely to provide food more economically and with better conservation of nutritional values than a multitude of domestic kitchens. The number of kitchen depots, dining-rooms, buffets, and cafés within the network administered by the Division of Public Feeding—a special branch of the Commissariat for Internal Trade—is estimated at about 60,000, and in addition there are many thousands of canteens and dining establishments under co-operative control. The kitchen depots are a noteworthy feature of the Russian arrangement. There is said to be one of these in each of the 27 districts of Moscow, and a similar number in Leningrad. They are centralized depots in which the food is prepared in all but its final stages—plucked, shredded, sliced, minced, as the case may be—and then transported in containers to the canteens. The final processes of cooking and service are under the control of the factory or school management. A point of importance is that the salvage of waste is largely concentrated in these preparatory plants.

The standards of efficiency in the canteens under State direction are primarily laid down by the Institute of Nutritional Research in Moscow, and cover not only the food supplies, but the kitchen space, the state of containers and crockery, the clothing and cleanliness of the staff. Many kitchen depots are equipped with chemical and bacteriological laboratories where the samples can be analysed. In the school canteens the equipment, personnel, and material are guaranteed by the Division of Public Feeding. A number of parents are on duty to help in the preparation of the school meals, to inspect the food and kitchens, and to assure themselves that the quality and quantity of the helpings are up to the standard prescribed, with an appeal to the school doctor in case of doubt. It is also the duty of the doctor to arrange classes on food values for both children and parents.

An interesting feature of the Russian system is the special diets for workers suffering from various complaints. The number of workers receiving special diets in factory canteens averages 600,000. Grants are allocated to the amount of 110 million roubles a year from the social insurance fund to enable the consumers to meet the difference between the cost of these special diets and the ordinary canteen meal. The largest number of special diets cooked in any one canteen is eleven; in the majority of canteens it is four or five. In the mines the dietetic canteens are open for twenty-four hours a day to supply all shifts. As a result of the special diets it is said that in one district of Moscow where inquiry was made absences from work had diminished by 50% and improvement in health was noted in 85% of the workers concerned. The best results are said to be obtained in cases of gastric catarrh.

ENDOBRONCHIAL TUBERCULOSIS

Five years ago we drew attention[1] to three papers[2, 3, 4] in which the earlier clinical manifestations of tuberculous tracheobronchitis were first described, and its importance as a complication of parenchymal tuberculosis was stressed, as well as its relative frequency. The outlook for patients with this complication was then thought to be very gloomy indeed, particularly as collapse therapy was deemed to be contraindicated for most of them. Opinion in this respect has changed, as is obvious from a series of communications presented in 1941 at the annual meetmg of the American Association for Thoracic Surgery. Reviewing 100 cases, J. M. Chamberlain and J. Gordon[5] point out that endobronchial tuberculosis tends to run a self-limited course, and therefore the "healed" fibrostenotic stage is often seen in the presence of an uncontrolled parenchymatous lesion. Moreover, the stenosis itself is consistently followed by a series of irreversible complications—namely, emphysema, atelectasis, and bronchiectasis. It is therefore essential to recognize the bronchial lesion at an early stage by bronchoscopy, and then reduce the size of the pulmonary bed before chronic stenosis occurs. Pneumothorax is considered to be dangerous when the bronchial disease is severe and the large bronchi are involved, but the results from thoracoplasty have been good. Local application of silver nitrate to the bronchial lesion is often beneficial as an ancillary measure.

W. M. Tuttle, E. J. O'Brien, J. C. Day, and F. J. Phillips[6] have studied 92 patients with ulcerative or healed bronchial stenosis. All patients have been observed for at least one year: 32% are dead, and 33% are still considered "unstable." Sixty-nine of the patients showed ulceration of the lesion when first seen and were treated with 30% silver nitrate; in 70% of these the lesion healed. These authors confirm the relative value of pneumothorax and thoracoplasty in the presence of endobronchial tuberculosis. Pneumothorax was "adequate" in only 12 of the 47 patients in whom it was induced; the incidence of empyema and unexpanded lung was 32% and 47% respectively. Thoracoplasty yielded much superior results. It was carried out in 34 patients; in 20 the disease is now considered to be arrested, apparently arrested, or quiescent. Only 5 thoracoplasty patients are dead (14.7%), as contrasted with 13 of the 47 pneumothorax patients (27.6%).

J. Alexander, G. N. J. Sommer, and A. A. Ehler discuss in detail[7] the effect of thoracoplasty and pneumonectomy upon pulmonary tuberculosis complicated by stenotic tuberculous bronchitis. They conclude that there are in such patients certain clear-cut indications for, and contraindications to, both thoracoplasty and pneumonectomy, and that for some patients neither procedure can be used safely. When no contraindication exists to either operation, thoracoplasty is the better operation because the mortality is much lower and the percentage of apparent healing of the tuberculosis is much higher. Indications for lobectomy are also given, but the authors stress that in their opinion the indications for pneumonectomy or lobectomy for tuberculosis are rare: they have performed the former operation only twice, and the latter three times. They give the results among 38 patients with stenotic tuberculous bronchitis. It appears, not only from the papers referred to above, but also from the subsequent discussion[8] at the annual meeting, that thoracoplasty is the therapeutic measure of choice for such patients, provided certain contraindications are kept clearly in mind; and that lobectomy or pneumonectomy may occasionally be the better operation. Finally, we should like to draw attention to a recent paper by O. C. Brantigan, R. Hoffman, and D. F. Proctor,[9] in which the authors show that endobronchial lesions may, after closed pneumonolysis, produce a check-valve type of obstruction that results in rapid re-expansion of the lung and loss of the pneumothorax space; and that under similar conditions complete occlusion of the bronchus may occur and result in atelectasis. The authors advise routine bronchoscopy before adhesion-cutting with local treatment of any endobronchial lesion discovered.

FOOD YEAST

Considerable progress has been made in knowledge of the B vitamins, and as their activity is interrelated it may be desirable to administer all of them for either preventive or therapeutic purposes. Unfortunately in wartime the richest source of the B vitamins—namely, animal protein (meat, especially liver; eggs and milk)—is in short supply, and plant protein has therefore to be utilized instead. Plant protein, however, is deficient in some of these vitamins although it is rich in others, and recent research work has been directed to supplying those that are missing. It is known that micro-organisms build up all the B vitamins, and in addition that the nutritive value of the protein they contain is as high as that of animal protein. With these two facts in mind workers at the Chemical Research Laboratory of the Department of Scientific and Industrial Research set about selecting a micro-organism, from the many known to exist, which could be produced in bulk from the cheapest raw materials, would reproduce rapidly, and be harmless to man. Such an organism has been found in the product of waste molasses to which nitrogen in the form of ammonia or ammonium salts has been added. The product, known as "food yeast," contains as much as 50% of high-grade protein, approaching meat and fish protein in nutritive value. Of the four chief B vitamins it contains in microgrammes per gramme: aneurin 20, riboflavin 60–80, pantothenic acid 60, and nicotinic acid 400–450. When dried it is a flaky substance, light straw in colour, and has a slightly meaty taste. It can be mixed with water or milk, added to soups and stews, and can be incorporated into biscuits and into flour for the daily loaf.

It is not, however, proposed to manufacture it in this country at present, except for experimental work, but plant is being sent to Jamaica, where the first large-scale experiment is to be carried out, and towards which a preliminary Exchequer grant of £25,000 has been made. "Food yeast" will thus not be available here for some considerable time, but it is estimated that it could be supplied at 6d. a pound, and that half an ounce daily would ensure a sufficiency of the B vitamins. This product offers a solution to one of the problems which will face the United Nations after the war—namely, that of supplying large populations, whose animal stock has been depleted, with a food containing a high concentration of the vitamin B complex and a high-grade protein. It will also be of value in tropical and subtropical countries, where native diets are invariably lacking in these constituents.

AWARDS FOR BRAVERY AND DISTINGUISHED SERVICES IN BURMA

Dr. Jehangir Ardeshir Anklesaria, port health officer, Rangoon, Dr. Douglas James Lapping, medical officer, Jokai Tea Company, Panitola, Assam, Dr. James Wallace Lusk, medical practitioner, Rangoon, and Dr. Arthur Mobsby, assistant district health officer, Mandalay, have been appointed M.B.E. (Civil Division), and Mr. Amar Singh Gill, sub-assistant surgeon, Mandalay Hospital, has been awarded the G.M., for bravery and distinguished services in the Burma evacuation. The official citations in a *Supplement* to the *London Gazette* dated Jan. 29 read as follows:

"Mr. Anklesaria went to Monywa, the base camp for the Chindwin evacuation, on special anti-cholera duty. He worked there for nearly two months in very trying and difficult circumstances and, by his outstanding devotion to duty and marked administrative ability, dealt very successfully with a serious epidemic outbreak of cholera, which at one time threatened to close down the Chindwin entirely as an evacuated route."

"When air evacuation from Myitkyina to Dinjan started, with only the briefest of notice, there was near the aerodrome a military hospital of 50 beds only. In a few days Dr. Lapping organized hospitals with a capacity of 650 beds and mobilized staff ready to deal with 1,800 wounded soldiers who were flown to Dinjan within a period of three weeks. Following on this, there set in the refugee evacuation through Ledo which, owing to the severity of the conditions and the climate, produced a high percentage of seriously sick. These also were taken care of by the organization built up by Dr. Lapping. A difficult situation was promptly met and it was due to the resource and organizing ability of this doctor that what might have been a calamity was in fact averted."

"Dr. Lusk took over at a moment's notice the Contagious Diseases Hospital in Mandalay, which contained over 200 cholera patients and was staffed by only one Indian doctor, one nurse, and one ward boy. He then took charge of the medical arrangements of all the evacuation camps in Mandalay and, although the commercial centre of the town was deserted and in many places burning, he managed to obtain adequate medical stores to stock all camps and even to send supplies to other camps up country. In a little over two weeks he managed to reduce the daily number of deaths in the Mandalay camps from 500 to less than 20. On April 26 he was the only civilian doctor remaining in Mandalay, and attended to all the casualties at the foreshore resulting from the air raid on that day. He worked without ceasing for 18 hours, and on the next night accompanied the wounded to Katha. He continued his services to evacuees along the railway line and from Indaw to Pyinbon, and drove lorries distributing rice to refugees on that route. Throughout the campaign Dr. Lusk showed courage, endurance, and organizing ability."

"Dr. Mobsby worked unceasingly in the cholera and small-pox camps and responded to all the extremely heavy demands made on him. He remained with the organization until Mandalay was evacuated, and continued his duties at Kyaukmyaung, Ye-U, and finally at Tamu camp on the Burma–Manipur border. He displayed unfailing cheerfulness throughout, and his readiness to perform work not falling within his immediate duties was of the greatest value to the evacuee organization."

"During an air raid on Mandalay the hospital was the centre of the target area and received several direct hits from incendiary and high-explosive bombs. Mr. Gill was giving an anaesthetic during an operation when the theatre was hit. Although suffering from shock he remained with his patient and eventually got him down to safety. He returned and brought out another patient who was awaiting an operation. He then helped to extricate from a burning building six night nurses and two cholera cases, although it appeared that to reach the building would be almost certain death. He afterwards set to work, without rest, to salvage hospital equipment. Mr. Gill showed cool courage and great devotion to duty."

Special attention to the food provided in industrial canteens for boys and girls from 14 to 18 years, particularly to the proper distribution of available foodstuffs, is urged in an article on canteens and nutrition in the Jan.-Feb. issue of *Industrial Welfare and Personnel Management*. It has evidently been the case in some instances that more meat has been served to those who could afford to pay higher charges for their meals than the "under 18's," that too much of the available milk has been used for coffee, and that the fat content of puddings and main dishes has been skimped to get pats of butter. In such methods the writer of the article sees lack of understanding of the needs of juveniles, and points out that more care in this direction will be amply repaid by less sickness, better production, and fewer accidents. In the same issue the establishment, within the boundaries of a factory, of a special ante-natal clinic which is attended regularly by a consultant obstetrician and gynaecologist is discussed. Two other articles deserve mention: one states the case for increased rather than reduced subsistence allowances for workers as illness continues, and the other describes the three centres established in 1942 which provide, at an inclusive charge of 25s. a week, "restful holidays" for workers suffering from nervous strain.

Reports of Societies

NON-SPECIFIC EPIDIDYMITIS

At a joint meeting of the Sections of Surgery and of Urology of the Royal Society of Medicine on Feb. 3 the subject for discussion was "Non-specific Epididymitis." Mr. E. C. Hughes presided.

Mr. E. G. Slesinger said that by "non-specific" was meant a non-tuberculous, non-gonococcal epididymitis, a well-recognized condition, although it had received scant mention in textbooks or articles. During the last fifteen months he and his colleagues had had 34 Service cases in men with an average age of 38.8 years. The symptoms were pain and swelling; in 19 the pain came first, in 8 the swelling, and in 7 the pain and swelling came together. The onset was gradual in 3 cases, but in the others it was stated to have been sudden. Some of the cases were febrile throughout, but most showed a marked pyrexia for the first few days; none of the patients appeared to be generally ill. There was tenderness in all cases, which was acute in 3. The vas was demonstrable in 16 cases, and the whole epididymis was enlarged in every case. Examination of the urine showed a little albumin in 12, and coliform organisms were seen on a slide in 3. Treatment consisted of rest in bed with support of the testis, the patient being fitted with a suspensory bandage. Sulphapyridine and sulphathiazole were tried, but neither made the slightest difference to the condition. Three cases were operated on. The results in the other 31 cases could be grouped as: (1) those in which resolution occurred in from three to six weeks; and (2) those in which resolution was a matter of some months. In the second group some residual thickening was left in the epididymis; but he had been unable to follow up the majority. He considered that this series represented something new in incidence, and in the absence of evidence of breakdown and obvious tuberculosis elsewhere it was certain that cases of epididymitis must be conservatively treated in the first instance. Operation was not essential in any of the 3 cases in which it was performed. The lumen of the vas seemed to be the route of the infection; there was no evidence that infection occurred by mass lymphatic spread. What was not clear was whether urine alone could produce an epididymitis or whether infection of the urine was a necessary concomitant. If all these 34 cases were really cases of infective epididymitis with pathogenic organisms, it was difficult to believe that none of them would have gone on to the formation of pus. If the passage of uninfected urine down the vas were accepted as the determining factor, there was nothing to explain why it should occur with such relative frequency in young men in the Services as compared with the normal population in peacetime.

Three Groups of Swellings

Mr. Donald McGavin said that the clinical group of hard, craggy swellings of the epididymis could be divided into inflammatory, obstructive, and vascular, and by far the largest group was the inflammatory. The ages of the patients varied from 24 to 38. In 3 of his small group of cases the onset was associated with strain while exercising or lifting. There were only 2 obstructive cases, one in a patient with a history of gonorrhoea who had a nodule on the side corresponding to the enlarged epididymis, and the other showed much muscular hypertrophy around the vas and tubules. In the vascular group the swelling often appeared to be in the body of the epididymis or in the upper pole. The prostate and testicle showed irregularity of form in some cases. In the inflammatory group 12 cases treated conservatively resolved, either completely or with a residual nodule in the lower part of the epididymis; in the vascular group 2 cases treated conservatively subsided satisfactorily. Treatment should include full investigation, with complete *x*-ray examination of the chest and other parts involved, and repeated observation each week and then at monthly intervals. Rest was important in the early stages, with modified activity in the course of three or four weeks.

Mr. R. H. O. B. Robinson said that non-specific epididymitis developed either with dramatic suddenness or insidiously.

Resolution was variable, in some cases lasting months, and there was a tendency to relapse. The condition might be bilateral, but was usually unilateral. Infection might come from the urinary tract, particularly the posterior urethra, as in gonorrhoea; non-specific urethritis and prostatitis might be responsible in others. Cases admitted to St. Thomas's in the period 1933-9 numbered 176, the majority of them non-specific. Of 50 cases under his own care during that period, 24 were non-specific, the remainder being tuberculous or gonorrhoeal, but at one hospital in 1941-2 21 cases were admitted, of which 19 were non-specific. With regard to the path of infection, the possibility of retrojection of sterile urine, with a small quantity being forced along the vas, had been suggested, and there was some evidence in American literature to substantiate this.

Brigadier HEDLEY WHYTE said that this was no new disease, and it was sufficiently common to be important. From the patient's point of view the medical attendant should realize that he was not dealing with a condition which necessitated the removal of the testis. He was not convinced that this was a disease peculiar to soldiers, and gave figures for military hospitals suggesting that the incidence was very small. Two different varieties of case from a clinical point of view were under consideration: he did not know whether one of them was a blood infection or due to retrojection into the vas, or the other due to direct spread along the vas from other urinary conditions; certainly some came on very gradually indeed, and might be mistaken for tuberculosis; others might be mistaken for torsion of the testis. Time was the great factor in establishing the diagnosis; the non-specific cases recovered, the tuberculous ones did not. With regard to treatment, in most of the cases there was a very acid urine and relief was obtained by alkalis. In a few cases there was general disturbance and rise of temperature and a good response to the sulphonamides. Wing-Cmdr. AINSWORTH DAVIES mentioned 58 cases which had been treated at an R.A.F. hospital and were divided into: (*a*) epididymitis secondary to diseases of the urinary or genital organs, and (*b*) epididymitis primary so far as the urinary and genital tracts were concerned. The primary type, which accounted for 37 of the cases, seemed to be due to a blood-borne infection, possibly from the colon, or following inoculation, or, rarely, a sequel of injury. When an obvious focus was present the epididymitis was probably staphylococcal. A few cases showed rise of temperature. The stay in hospital averaged 14 days.

Response to Sulphonamides

Wing-Cmdr. G. L. M. MCELLIGOTT said that since the introduction of the sulphonamides gonococcal epididymitis was extremely rare, but he saw more cases after non-specific or non-gonococcal urethritis than after specific gonococcal urethritis. Probably the best explanation of how the condition was acquired was that the original source was a gonococcal infection which cleared, leaving behind a secondary inflammation, from which the condition was picked up. Coliform organisms were found in very few of these cases. A significant point was that the cases relapsed; the swelling went down, and the patient went on leave, and was back again in three or four weeks, with or without an accompanying urethritis. This might be extremely slight and might well be missed unless examination took place in the early morning. The duration of disability might be lessened considerably by short-wave therapy to the epididymis.

In some further discussion Brigadier EDWARDS asked whether they were quite safe in assuming that the patient recovered by rest in bed. Col. T. E. OSMOND suggested that all these cases should undergo a puncture of the epididymis and a bacteriological examination. He had found diathermy give great relief. In his reply Mr. SLESINGER said that they were all agreed that the textbooks and teachers of the past had not been alive to the fact that the epididymis was heir to many ills other than those due to the gonococcus and the tubercle bacillus. Another thing which the discussion had brought out was that a number of different things were still being confused under the one heading. It was important to recognize that these cases occurred a great deal more often than was appreciated. He suggested that men in the Services should be advised to empty the bladder before doing physical training.

RECENT EXPERIENCE OF ENCEPHALOMYELITIS AND ALLIED CONDITIONS

At a meeting of the Section of Neurology of the Royal Society of Medicine on Feb. 18, with Dr. R. M. STEWART presiding, the subject for discussion was "Recent Experience of Encephalomyelitis and Allied Conditions."

Dr. W. RUSSELL BRAIN said that the clinician was much handicapped in discussing acute encephalitis. The textbook presented him with an elaborate classification based upon pathological differences, isolation of viruses from the brain, cross-immunity tests, and so on, but the clinical descriptions of the various forms closely resembled one another. Hence, apart from epidemics and the post-exanthematous group, any clinical diagnosis that went beyond acute encephalitis was often only guess-work, and if the patient survived and no virus was isolated it could not usually be said with what form of encephalitis they were dealing.

During the last two years he had seen 22 cases of acute encephalitis and 6 of acute aseptic meningitis. Of the 22 cases of encephalitis, 6 followed measles, 1 mumps, 2 occurred after inoculation, and 2 were of the so-called Marie-Strümpell type. The remaining 11 seemed to fall into 3 clinical groups. In 6 the onset was acute or even fulminating with high fever and stupor or coma, and 3 of them with meningeal signs had polymorphonuclear cells in the cerebrospinal fluid; in spite of the stormy onset, recovery was complete in 5. In 2 further patients the onset was subacute and the course progressive to death in two to three months. In the remaining 3 the onset was subacute and the course at first relapsing; there was evidence of considerable destruction of the white matter with permanent visual-field defects and pyramidal lesions when the disease became arrested. Without attempting to apply clinical descriptions to them, it might be said that there seemed to be three different patterns of reaction of the nervous system to infection.

An interesting cerebral complication of scarlet fever was a meningo-encephalitis characterized by a lymphocytic pleocytosis. He recently saw an example of this in a boy of 6 who developed meningeal symptoms when his rash was desquamating. He was febrile for ten days and showed no response to either antistreptococcal serum or sulphonamide. His cerebrospinal fluid contained 160 lymphocytes per c.mm on two occasions. Was this meningo-encephalitis caused by a streptococcus or its toxins, or was it caused by a virus? and if by a virus, was the virus infection superimposed upon scarlet fever, or was the whole disorder, including the rash, due to a hitherto unrecognized virus?

His series included one example of a rare form of encephalitis of which only 4 previous cases appeared to have been described. The characteristic feature was the presence of eosinophil inclusion bodies in the nuclei of the cortical ganglion cells. His patient, a boy of 11, developed symptoms after anti-diphtheria inoculation. Change in character was followed by impaired vision and ataxic gait. The distinctive clinical features were facial spasm, trismus, clonic movements of the right upper and lower limbs, and a right grasp reflex with left hemiparesis. The patient was comatose with double hemiplegia for five weeks before he died, three months after the onset of symptoms. The cerebrospinal fluid was normal.

Little had been added to existing knowledge about encephalitis after measles and other exanthems. He had seen 6 cases of measles encephalitis in the last two years, and had learned that complete recovery might occur from a condition which during the first weeks of the illness looked hopeless. A girl aged 12 was mute and diplegic six weeks after the onset of encephalitis, but three months later she had almost completely recovered. It was difficult to assess the results of treatment, but it was advisable to use convalescent or immune horse serum.

He had seen 3 cases of nervous disorder after inoculation with tetanus toxoid with or without T.A.B., and 4 cases of nervous disorder occurring within a few days of A.P.T. inoculation against diphtheria. One of these was the fatal case of encephalitis with inclusion bodies already described; the other 3 were all cases of poliomyelitis, occurring when this disease was already prevalent. The relation of the infection to the inoculation was at present unsettled, but it should be emphasized that with diphtheria immunizations numbering thousands and

T.A.B. and tetanus toxoid inoculations numbering millions these complications were extremely rare. Finally, it should be borne in mind that sulphanilamide might cause demyelinating lesions of the brain and spinal cord, and as drugs of this group were now so widely used in the treatment of acute infections, care should be taken before attributing to the infection an encephalopathy which might be the result of the treatment.

Dr. J. G. Greenfield showed a number of microscopical sections taken in cases of encephalitis and indicated the form and nature of the inclusion bodies. One of his cases was an encephalitis which he regarded as being of the virus type, and which corresponded histologically with encephalitis produced by known viruses but differed considerably from the accepted picture of encephalitis lethargica. It was in a boy of 9 who died three days after admission to hospital; he had no fever until a few hours before death, and the cerebrospinal fluid was normal. Microscopically a very intense encephalitis was found with marked microglial infiltration.

Dr. Dorothy Russell also showed a series of sections, including ones illustrating the inclusion encephalitis to which Dr. Greenfield had drawn attention. This was a particularly interesting form of encephalitis because it seemed to bear all the hall-marks of a virus encephalitis. There was nothing very gross to be observed, and it was peculiar in that there was very little associated meningitis. In the pyramidal cells of the cortex there were a considerable number of eosinophil nuclear intrusions.

The President said that it was obvious that this aspect of neurology must account for a very important chapter in the textbooks of the future. He raised the question of Schilder's encephalitis.

Dr. Russell Brain said that one of his cases of encephalitis following measles was exactly like Schilder's encephalitis in its end-result. There were, however, two attacks, the first of them three weeks after measles, when the child ceased to speak, but there was no coma and there was a gradual return to normal. After a lapse of nine months the child became ill again, had coma, which remained for a week or so, and on recovering consciousness was completely blind, and the end-result was exactly like that seen in a case of Schilder's encephalitis.

NUTRITION IN PREGNANCY

The Nutrition Society held its tenth meeting at the London School of Hygiene and Tropical Medicine on Feb. 6, when the subject of the symposium was nutrition in pregnancy. The chair was taken in the morning by Dr. F. H. A. Marshall and in the afternoon by Brigadier F. A. E. Crew. There was a large attendance at both sessions, the agenda for which included six short papers, five separate discussions, and a general discussion.

Mr. Aleck Bourne opened with a paper on foetal development, in which he sounded a warning note against the tacit assumption, made by many who should know better, that birth weight was necessarily an indication of viability and health. As was pointed out by many subsequent speakers, though there were others who seemed to have forgotten it, the effect of sub-optimal maternal nutrition—at any rate in the human species—only makes itself felt in the offspring if the nutritional plane is so low as already to have affected the health of the mother adversely. This is a particular aspect of a general rule—one of the few that seem to emerge clearly from the mass of information brought forward at the meeting—to the effect that the foetus is essentially parasitic on the mother. Dr. John Hammond attempted to bring a general and more theoretical interpretation to play on the facts summarized in this way. His suggestion that the flow of nutrients to any tissue or organ was determined by the metabolic activity of that organ, and that this principle applied not only to the single organism but to the mother and foetus treated as one, certainly seemed to explain many of the known facts, or at least to summarize them in a concise and intelligible manner. At the same time, as Dr. Hammond himself was the first to admit, the differences between species still need explaining, especially as these result both in very marked differences of development as between the newborn of one species and another and also in marked proportional differences between the various parts of the new-born body. Generally, however, these differences correspond closely with those in maturity of the embryo at term.

Functions of the Placenta

Dr. Hammond's paper was followed by a characteristically speculative survey by Sir Joseph Barcroft of the nutritional functions of the placenta. He asked many questions to which he said, regretfully, he was unable to supply answers, but his paper did serve to show the gap between the practice of the obstetrician and the experiments of the physiologist, bridged to a limited extent by the workers in animal husbandry and the laboratory biochemist. Sir Joseph raised the question whether the placenta was to be regarded merely as an ultra-filter, or whether it had powers of discrimination that affected the relative rates of passage of various nutrients, and, if so, how such powers were achieved. The figures given by him of the relative differences in pressure between oxygen in maternal and foetal blood vessels, differences in osmotic pressure between the two plasmas, and differences in individual ion concentrations, seemed to indicate fairly clearly that the placenta was something more than a mechanical barrier. In opening the discussion on Sir Joseph's paper, Dr. T. Moore called attention to the barrier offered by the placenta to vitamin A, and it was recalled during the discussion that a similar phenomenon had been recorded for vitamin E.

The first three papers constituted the main part of the morning's business and each led to brisk discussion. Several speakers referred to the unsoundness of attempting to ease labour by reducing the size of the infant through nutritional deprivation. It is clear that this procedure has now the active opposition of all leading experts both in the gynaecological and in the nutritional field. Dr. A. S. Parkes, in an interesting note contributed in his absence by Dr. Ruth Deansley, discussed the bearing of hormone-induced superfecundation in rabbits on the problem of infant size, and came to the tentative conclusion that this was more likely to be determined by nutritional factors than by hormone supply.

At the afternoon session, at which attention was given to the relation between parity and infantile mortality and morbidity, Prof. James Young, answering Dr. S. K. Kon, said it was impossible to state whether there was any real correlation between the birth weight and parity in the human subject. Dr. W. H. Newton referred to the effect of the placenta on the maintenance of maternal weight, and Mr. Aleck Bourne emphasized what he had mentioned in his original paper—namely, the importance of sound nutrition as a means of securing proper uterine function, normal labour, and viable offspring.

Wartime Diet: Its Likely Deficiencies

In a paper on diet in pregnancy Prof. A. St. G. Huggett stressed the importance of the last period of pregnancy, and discussed in some detail the effect of planes of nutrition on the health of human and other animal infants. After considering wartime statistics and diets, he tentatively concluded that the only likely shortages in the present-day feeding of pregnant women, compared with pre-war feeding, were in animal protein, calcium and phosphorus, vitamin D, and ascorbic acid, but that the deficiency, if any, of each of these was not enough to have affected significantly the birth weight of newborn infants, even of twins, which normally afforded the more sensitive index. Prof. Huggett's paper was appropriately followed by a summary from Dr. Margaret Balfour of the well-known Birthday Trust Fund experiments. Dr. Balfour's statement made it clear that the final parts of this investigation had benefited from the investigators' experience during the earlier stages, and had thus made possible detailed statistical examination and treatment of the results. These showed the effect of supplementary feeding on the health of babies and also of their mothers when these had been previously subjected to a diet considered inadequate by modern standards. The results of this investigation thus afford in some measure an *ex post facto* justification of the People's League of Health and the Toronto experiments, both of which have been adversely criticized recently, as Prof. Huggett and also Prof. J. R. Marrack pointed out, without adequate consideration being given to the relation between these admittedly limited experiments and the whole body of present knowledge about diet and health in general and pregnancy in particular.

Mr. RICHARD TITMUSS presented a paper on stillbirth and neonatal mortality, in which he had collected data on the bearing of various influences on both mortality and morbidity of the infant. His figures, which will need detailed study when they are available in print, revealed the effect of a number of, perhaps, previously unsuspected factors—such as the difference between town and country—and showed that preventable wastage of infant life still goes on. He posed some interesting questions—for instance, why there appears to be an "irreducible minimum" of neonatal death and why the differences in social ranging express themselves in an increasingly different mortality rate between infants of increasing age.

Of particular interest during the general debate was a discussion between Dr. ISOBEL LEITCH, Dr. HELEN MACKAY, Prof. HUGGETT, Dr. LUCY WILLS, and others on the relation between the iron content of human milk, the iron reserves of infants, and the susceptibility of infants to anaemia. Prof. E. J. BIGWOOD'S information to the effect that birth weight in Belgium on a maternal diet of 1,500 to 2,000 calories per day had not substantially diminished seemed to give effectual denial to the assertion, quoted by Prof. Huggett, that birth weight in Vichy France had fallen by one-third. For this there appears to be no documentary evidence. The possible relation between the creatinuria of pregnancy and vitamin E deficiency was, unfortunately, side-tracked into a wholly irrelevant discussion on muscular dystrophy.

Correspondence

Scientific Freedom and Social Medicine

SIR,—As a member of the Medical Planning Commission I have read with very great interest, and perhaps a little surprise, the article by Dr. Geoffrey Bourne (Feb. 20, p. 227) and the letter by Mr. T. W. Mimpriss (p. 234). The fears which Dr. Bourne so ably expresses are and have been in the minds of every member of the Commission. They have not only been acutely aware of the dangers but have been very apprehensive lest they should be grafted on to the new system of social medicine. My feeling of surprise lay in the fact that so many of the profession do not appreciate how all the grave drawbacks of State medicine described by Dr. Bourne have been most fully and carefully discussed, and the precautions suggested to avoid them have been published in the Interim Report, which together with the conclusions of the committees have been published in the *Journal.*

It is manifest that this report has not yet been sufficiently widely read, and Dr. Bourne's article will therefore be invaluable in directing attention still more forcibly to the fact that with State control of medicine, as conducted in the present autocratic manner, there is a very real danger of the complete loss of freedom of thought and freedom of action, that criticism and with it all progressive work may disappear, and that the profession may become simply a system of distributing the knowledge gained by other countries free from the trammels of bureaucracy. It may also be of value to those who are not aware of what has been done to consider seriatim the conclusions of Dr. Bourne, with which I may say I am in entire accord, and to give references to those sections of the Interim Report in which methods of avoiding the dangers are suggested.

(*a*) All the higher posts are purely administrative. This is true of the majority of State services; even in the Army no one above the rank of lieut.-colonel is an operating surgeon or a clinician. All conduct is strictly controlled by orders laid down in King's or other Regulations drawn up by those with but little clinical and no local knowledge, situated at a remote centre. The clinical head is given no responsibility of action but is responsible for his actions. He may have gained excellent results, but if to do so he has contravened some foolish rule he is reprimanded rather than commended. As a result, not only does all initiative disappear but able young men refuse to enter a service in which after a time all their clinical and scientific training is lost and they become stereotyped civil servants. Nearly all medical superintendents in the present State services are acutely aware of these drawbacks. (See sections 38, 39, 41, 79, 80.)

(*b*) Control of the service is in the hands of one man, generally a layman, at the head with autocratic powers, or of a lay body. This is an extension of (*a*), but it tends to limit progress and improvement, and especially improvement based on the experiences gained by those in clinical posts and by professional men abroad. The profession tends to be stereotyped and economic rather than live and progressive. (See sections 51–60.)

(*c*) Control of the institution is in the hands of a medical superintendent. Unless the superintendent is a man of wide vision, all research and originality in the younger men have no scope, nor do they develop a sense of responsibility or the power to rectify abuses and the use of out-of-date methods. The superintendent is expected to be a supernatural being with a knowledge of all branches of medicine, which is beyond human capacity. (See section 89.)

(*d*) No action can be taken or newer scientific methods be used without permission. Hence there is a long period between the acquirement of knowledge and its practical use. (See sections 89 and 82–84.)

(*e*) Freedom of publication. The absence of this is almost universal in all the present State services. Permission has always to be obtained, and has in the past been withheld because the article has been thought to criticize the methods of the service. The importance of freedom of action, of thought, and of speech has been universally recognized and insisted upon by the Commission, and its loss has been guarded against by the sections dealing with the positions of the members of the staffs of all hospitals in the scheme. (See sections 78–94.)

(*f*) The danger of political pressure. With Government control and with the highest post a reward given by the political party in office this is a real danger. Its worst results are seen in Germany, where eminent scientists have been replaced by inefficient heads who are ardent Nazis.

(*g*) Promotion by seniority. The danger of this system, which is present in all the State medical services and is characteristic of all bureaucracies, has been recognized as perhaps the most important factor in crushing all initiative and originality and as being likely to reduce the present high standard of British medicine to mediocrity. Men, whatever their ability, have to relinquish a post on reaching a given age or after holding one post for a certain period—in the Army medical it is four years—in order to make way for the promotion of a younger man who in many cases has no claim other than length of service. Rank or emolument is not given to the man but is carried by the post, so that a man's rank or reward may alter not from a change in his ability but because a regulation insists on his being moved from post to post. (See sections 87, 88, 92, 93.)

(*h*) Mr. Mimpriss's letter deals with the question of private fees of salaried officers. The claims of some services that fees paid by private patients, attracted by the skill, reputation, and renown of an individual doctor, should be paid to the service which pays his salary, although it already makes a profit by the letting of the private room, is recognized as an iniquitous exploitation of the doctor. (See section 83 and the later conclusions of all the recent committees as published in the *Journal.*)

Finally, all these dangers are guarded against by the proposals of the three later committees that the Commission would be willing to co-operate . . . provided that the character, terms, and conditions of the medical service are determined by agreement with the medical profession.—I am, etc.,

London, W.1. JAMES WALTON.

SIR,—I think Dr. Geoffrey Bourne (Feb. 20, p. 227) merits our warmest congratulations on his notable article on this subject. He has suggested one foundation stone—*scientific freedom*—as essential to a new medical edifice if it is to make a maximum contribution to the health of the people. Of course, there are other foundation stones about which opinions are divided; but unanimity in the profession in support of Dr. Bourne's thesis would probably go far to secure its adoption if its intrinsic merit alone failed to carry conviction.

Bacon long ago laid down that "no pleasure is comparable to standing on the vantage ground of truth." That a youthful genius, so standing, should be frustrated by a short-sighted autocrat is unthinkable, and no doubt adequate safeguards could and would be devised.—I am, etc.,

Manchester. J. STAVELY DICK.

SIR,—It was a pleasure to read Dr. Geoffrey Bourne's article "Scientific Freedom and Social Medicine" (Feb. 20, p. 227). May I give an early experience of the autocratic system? I was an assistant medical officer at a fever hospital in pre-antitoxin days. At 2 a.m. on a winter's morning I was called by the night superintendent to a little girl suffering from laryngeal diphtheria. I had admitted the child in the afternoon and had obtained the written permission of the parents for tracheotomy if necessary. The child, aged 3, was *in extremis* and I operated, the anaesthetic being given by a junior (qualified) colleague. Later in the morning I was summoned to the office of the medical superintendent and soundly admonished for not having obtained his permission to operate. I should say that his house was at least a quarter of a mile from the ward and there was no telephone. I was threatened with "suspension" and was to be reported to the chairman at his next weekly visit for luncheon (and billiards). No more was heard of the matter, for the tube was out in four days and the child made a good recovery. I only learned later that mine was the first tracheotomy that had survived at that hospital.

Dr. Bourne refers to publications by medical staffs, but he omits to mention that officers of the L.C.C. hospitals not only had to obtain the permission of the Chief Medical Officer before publishing any communication, but further had to state that the Council assumed no responsibility for the (approved?) opinions expressed by one of their officers.—I am, etc.,

London, S.W.1. JAMES H. SEQUEIRA.

The B.M.A. and the Beveridge Report

SIR,—No doubt we all realize the difficulty the Council of the B.M.A. faced in framing their recommendation, but surely the one decided upon will be immediately "blown sky-high" by the obvious question:

> "If, as suggested, there are members of the community who decide not to avail themselves of the benefits of the scheme, but wish to obtain their medical service from a doctor within the scheme by paying privately, what advantage would such patients expect to gain from their doctor by such arrangement which they would not otherwise receive?"

—I am, etc.,

Halesowen, Worcs. HERBERT W. BLAND.

SIR,—I think that if the Beveridge report is brought in in full then the medical profession should co-operate fully with the Government in providing a complete medical service for the whole community; but we as a profession should be united on one point—namely, that the conditions of service must be satisfactory and must be agreed upon by previous negotiation between the medical profession and the Government.

The conditions of service should be such that a doctor is adequately paid, so that he can fulfil his existing obligations and continue to live in a style to which he has been accustomed; he shall have sufficient freedom to carry on his practice in a manner agreeable and convenient to himself and his patients; and, finally, the clerical work should be drastically curtailed. Previous negotiation is essential, as we do not wish to find that, after contracting to fulfil certain obligations, other obligations are thrust upon us without our consent being obtained.

If, however, the Government attempts to bring in the medical part of the Beveridge report alone while deferring the other proposals, then I think we should be better advised to press for the B.M.A. plan, with its consultant service for N.H.I. patients and the inclusion of their dependants. This will give an inexpensive and good medical service to those who really need it, and will not interfere with the existing arrangements between doctor and private patient.

Whether the Beveridge report or the B.M.A. plan is brought in, I think we should insist on three things: (1) The conditions of service must be satisfactory and must be agreed upon by previous negotiation. (2) The scheme should rest upon a general practitioner basis, and should provide for part-time State salaried service and part-time private practice. (3) There should be free choice of doctor and free choice of patient in order that the doctor may serve the patient and not the State alone.

We should avoid a whole-time State salaried service, which is contrary to the traditions of our profession and the interests of our patients, and which means, for us, service on terms dictated by the Government, since we as a profession would have no prospect of employment other than Government service.—I am, etc.,

Stonehouse, Glos. W. G. MURRAY-BROWNE.

War Neuroses

SIR,—In his paper on war neuroses (Feb. 13, p. 183) Dr. W. Ronald D. Fairbairn expresses his belief that they are the result of regression to an infantile emotional level, in which the soldier regards his superiors in rank as "bad" parental figures who have no love for him, in contrast with the "good" parental figures at home who love him. He looks upon the neurosis as the result of an attempt to restore emotionally the intra-uterine state of security which was rudely disturbed by the experience of birth. Holding such fantastic beliefs it is easy to understand why Dr. Fairbairn finds that the war neuroses are resistant to his psychotherapy.

My experience in the war of 1914-18, and especially at Seale Hayne Military Hospital for Functional Nervous Disorders with its 350 patients and 10 medical officers, was that the war neuroses responded very well to simple psychotherapy in the form of explanation, persuasion, and re-education. Major W. Johnson and other officers in charge of advanced neurological centres in France were able with similar methods to send 60 to 80% of their patients back to front-line duty within four weeks of the onset of symptoms, and according to Col. Gordon Holmes only about 10% relapsed.

A much smaller experience in the present war has not led me to alter my opinion. The results achieved by the late Col. E. L. Cooper and Capt. A. W. M. Sinclair (*Med. J. Austral.*, 1942, 2, 73) during the siege of Tobruk have shown in dramatic fashion how good is the prognosis of war neuroses when properly handled, even under the most unfavourable conditions. They worked in a special ward situated in a dimly lit concrete shelter near a heavy anti-aircraft battery, where psychotherapeutic talks were punctuated by the noise of shell fire and bombing, and where there were no facilities for recreation or occupational therapy. In spite of these disadvantages 79 out of 207 men with war neuroses treated between May and August, 1941—i.e., 38%—were returned direct to their units. An additional 48 went back to full duty after treatment at the base, making a total of 61% now serving as fighting soldiers. Of the remainder 23% were fit for base duties and only 12% (of whom 7% were mental defectives or psychotics) had to be evacuated to Australia.—I am, etc.,

Oxford. ARTHUR HURST.

Abortus Fever

SIR,—I read with interest Dr. D. G. Leys's article (Feb. 13, p. 187) on eight cases of abortus fever. During 1941-2 I saw five cases of this infection, four of which came under my own care and one was seen in consultation. All patients were over 21 years of age, and four were males, thus conforming with the general trend that the under-15's and females are more immune. Dr. Leys's cases, in the main, conformed to this distribution.

Three of the five cases were definitely diagnosed as of abortus fever by their own doctors, a fourth was admitted as a paratyphoid B infection, and a fifth as a case of cerebrospinal meningitis. Three of the cases had "rose spots," and in two instances these were numerous. All complained of general muscle aching, profuse perspiration, and severe headache. Titres ranged from 1:480 to 1:2000 (highest tested). The case admitted as of cerebrospinal meningitis had neck rigidity, marked photophobia, and drowsiness lasting for 48 hours. One patient died; he developed an acute left orchitis, followed by a right pleurisy, then a left pleurisy (both sterile), and, finally, meningitis (sterile), considered on chemical analysis of the cerebrospinal fluid to be tuberculous. Both spleen and liver were enlarged. Orchitis is also noted as a manifestation of infection in bulls, rams, and boars, while muscles are affected in equines. The occupations of the patients were as follows: engineers 2, airman 1, W.A.A.F. 1, lawyer 1.

Treatment was with sulphapyridine 8 to 10 g. daily, reducing the dose as the temperature settled. In the case of the patient who died, fouadin was also used, but without effect. The average length of the illness after the commencement of treatment was four weeks. The doses of sulphonamides given by Dr. Leys to his cases have been, I think, too meagre, as a loading dose is required, followed by a tapering off in amount when the temperature begins to settle. From experience of the fatal case mentioned above and my knowledge of another case, not under my care, still active after three years, I feel that early and adequate treatment with all the necessary precautions is necessary, as once chronicity sets in sulphonamides may not be efficacious.

The true incidence of abortus fever is probably much higher than is generally believed, although in a rural area like Ross-shire the general practitioner, as a result of his close contact with a farming community and the diseases that affect their animals, is in all likelihood more aware of the possibility of its presence than is his colleague in urban areas.—I am, etc.,

Strathpeffer, Ross-shire. J. LANDESS HORNE.

Weil's Disease

SIR,—Dr. K. Blum's letter on Weil's disease (Feb. 20, p. 231) calls for some comments.

1. It is well known that many cases of Weil's disease never develop jaundice; in Holland, Schüffner found 60% anicteric. Therefore, while it is true, as Dr. Blum states, that "every case of illness with jaundice and high fever should be suspect," many cases will be missed if these are the criteria adopted. It must, however, be admitted that the early diagnosis of Weil's disease is very difficult except when the patient's calling attracts attention to the possibility—e.g. coal-miners, sewer-workers, fish-workers.

2. The agglutination test is negative until the 6th or 7th day of disease, and is often confirmatory rather than diagnostic. If specific serum treatment is to be of value it must be carried out during the first few days of the illness.

3. For diagnosis, in addition to a history of certain or probable contact with rats (in this country there has been no evidence that mice play any part), the blood count is of especial value. In Weil's disease there is a polymorphonuclear leucocytosis, whereas in infective hepatitis (catarrhal jaundice) the total white cell count is normal or diminished, and there is a relative lymphocytosis.

4. Dr. Blum states: "Whether ordinary infectious hepatitis in wartime is allied to morbus Weil cannot be proved, but should be borne in mind." In fact, although definite proof has not yet been obtained, the available evidence is strongly in favour of a virus origin of infective hepatitis, and there is no indication that it is in any way related to Weil's disease. Hundreds of cases have been investigated, mainly by my former colleague Major H. C. Brown, with this point in view.

5. In the past the investigation of the various "jaundices" has been badly hampered by failure to discriminate among the different clinical and pathological entities. These conditions are now being separated, and it would be a great pity if the position were to be obscured by reintroduction of the old confused ideas.—I am, etc.,

The Wellcome Research Institution, W.C.1. J. C. BROOM.

A Member Resigns

SIR,—Your leading article on "A Member Resigns" is a little too ingenuous to go without comment. Thus might Mr. Chamberlain or any of the tetrarchs of the 'thirties have said: "True we have the keys of office, the party machine, the Press, air, money, and time, yet we are a democracy and any of you can come and take our places."

The note about the imminence of the crisis that confronts us probably means that the older men are preparing to sell the pass while the younger ones are otherwise engaged.

Still I disagree with the resignation. The worst of quarrelling is that it stops controversy. Besides, I think the library is well worth the sub.—I am, etc.,

Beckley, Sussex C. G. LEAROYD.

SIR,—Like your original correspondent (under the above title) I recently entertained the thought of discontinuing my membership of the B.M.A. and for much the same reasons: on account of its silence during the present critical phase of our social evolution, and its failure to lead, to present a bold concrete total plan to meet the pressing demands for adequate health facilities for all. But I decided not to resign just yet, because, on stating the proposition to myself thus—"Knowing that adequate medical services should be available for all; and knowing that the high cost of such services could not be met except by the State, why does not the B.M.A., or its Council, present a comprehensive total scheme to Government accordingly?"—several obstacles then became apparent. First, the obvious lack of agreement among members of the medical profession itself; the conflict between the older conservative doctors hoping to continue private practice along the present lines and the younger generation favouring a sort of panel system for all. Another difficulty was that of estimating the cost; expenditure very much higher than at present would obviously be needed, but such estimates might meet with official rebuff as yet. In the circumstances a cautious advance by the B.M.A. was understandable. So I decided not to resign this year, and I am pleased, because otherwise I should have missed reading Dr. Geoffrey Bourne's article entitled "Scientific Freedom and Social Medicine" (Feb. 20, p. 227). The publication of this article reveals a healthy and progressive outlook—at least on the part of the Editor. One earnestly hopes that Dr. Bourne's lucid and instructive article will be widely read. Obviously it cannot be read by some thousands of non-B.M.A. doctors and by the public (non-readers of the *B.M.J.*). Therefore I would suggest that, say, 100,000 copies of the article be printed and distributed free Some of us would be pleased to contribute to the cost of printing, etc., if necessary.

Space does not permit one to quote from Dr. Bourne's essay, but one principle of fundamental importance which he sets down in italics should be stressed again and again, "The *democratic* system of medical service is *entirely compatible with State control.*" It is urgently desirable that all doctors should appreciate this truth.

In the same issue (p. 230) there appears a thoughtful and provocative letter by Dr B. W. Monahan, who recognizes that the most essential need in providing more extensive medical services is a monetary one, and he aptly points out that the average smoker spends £10 yearly on tobacco. One wonders what the total expenditure on beer and tobacco is, and how much it would cost to provide a comprehensive medical service for all?—I am, etc.,

Aldershot. F. M. PURCELL.

Foot-and-Mouth Disease in Man

SIR,—As has been widely publicized in the national newspapers, there has been a severe outbreak of foot-and-mouth disease in my county. An interesting sequel has occurred in my practice.

On Feb. 8 I was called to see a little girl in a small farm cottage. This house is adjacent to two small farms, at both of which recently there was an outbreak of foot-and-mouth disease among the stock, all of which had to be slaughtered. This child had to skirt these farms on her way to school daily. She was not in direct contact with the animals, nor was she drinking milk from either of these sources. The milk came from an attested source elsewhere.

On examination the child was very toxic, and in the room where she lay there was a peculiar pungent smell which intensified as one approached the bed. Her temperature was 103° F., pulse rate 150–160 per minute, respirations 23 per minute, and she was flushed and cyanosed. Excessive salivation was apparent, and the saturated pillow exuded this peculiar smell. She had become progressively ill for some days before I was called. On examination of her mouth I found that there were multiple vesicles and small yellow ulcers extensively over the inside of her lips and cheek, and on her palate and gums, the surface of the tongue, and on the pharynx The vesicles were filled with yellow fluid. The breath was very foul and some of the ulcers were bleeding. Apart from this the only other complaints were of abdominal discomfort and severe thirst Further examination revealed no other lesions on the skin Her lungs appeared to be normal. No laboratory tests were done, treatment being carried out straight away.

She was given a total of 12 grammes of sulphapyridine and dettolin mouth washes Her temperature and pulse settled to normal in 4 days, and on Feb. 14 her mouth was practically clear except for some shallow vesicles and ulceration on the gum margins around the teeth Our local medical officer of health, who saw the patient for me, was also of the opinion that this was probably a case of foot-and-mouth disease.

—I am, etc.,

Dingwall KENNETH MACLEOD

⁂ Two cases of foot-and-mouth disease in man were reported by Dr Henryk Dlugosz in the *Journal* of Feb. 13 (p. 189)—ED., *B.M.J.*

Rushcliffe Committee's Report

SIR,—An adequate nursing service is unlikely to ensue from mere attention to the pay packet. "There is no wealth but life," and money is no compensation for loss of health in youth. Until we realize that an impossible strain is imposed upon nurses by expecting of them two lives in one—the student's and the full-time employee's—we shall, deservedly, go short of recruits. The Rushcliffe Committee's recommendations do not reach the core of the problem.—I am, etc.,

ESTHER CARLING.

Dietetics of Pregnancy

SIR,—Your correspondents Mr. W. T. Russell and Dr. W. J. Martin (Feb. 13, p. 204) are right in supposing that my knowledge of statistical technique is imperfect. It is, however, sufficient for me to appreciate the cogency of their correction and to be able to agree with them that the sampling error in the work of the People's League of Health is even greater than I stated. Now the purpose of my contribution to the discussion at the R.S.M. was to examine critically the claims made by some recent workers to have influenced the incidence of premature birth by dietetic methods. I suggested that the results of the work sponsored by the P.L.H. had no significance. If the statisticians who examined them now state that I have ascribed to these results a higher degree of significance than they ever claimed, it seems that there is no point at issue between us.

As regards the data which I presented before the R.S.M., the abbreviated report does not, perhaps, make the point as clear as it might be, but I should have thought that with the aid of the published histogram the facts could be deduced. These facts are that the periods of gestation recorded in my series of 147 observations are normally distributed around a mean of 41.2 weeks, with a standard deviation of about 12 days; this *does* lead to the expectation that one-eighth of all instances will terminate before the beginning of the 40th week. Of course, a normal curve is not symmetrical about a line which is not drawn through its mean point; even I, the imperfect statistician, do not expect that.

Your correspondents' comment on the failure of the P.L.H.'s dietetic measures to influence the mean birth weight—"especially as all premature babies are not subnormal in weight"—affords a perfect illustration of the way in which the main object of a piece of work can be forgotten if realistic standards are not set at the start and rigidly maintained. Infants die from immaturity, not from estimated prematurity.

While I fully realize that Mr. Russell is not responsible for the choice of experimental method, surely the fact remains that the estimated period of gestation—estimated presumably from the last alleged menstrual period—is too crude and unreliable a yardstick by which to measure the small differences which these dietetic experiments have achieved. To desire earnestly that some means, dietetic perhaps, may be discovered for the prevention of premature birth and the wasteful loss of infant life associated therewith is not the monopoly of the P.L.H. or of any section of opinion; but to prove the efficacy of such means is another matter. It would not be unfair, I think, to liken these advocates of dietetic methods for the abolition of prematurity to the leader of the deputation who closed his interview with the Minister of State with the words, "And those, Sir, are the opinions upon which I base my facts."—I am, etc.,

London, W.1. DOYNE BELL.

SIR,—Dr. Doyne Bell's histogram does not represent a normal curve but a skew curve conforming to Pearson's Type I. Neither a normal nor a symmetrical curve can be expected to describe the length of gestation, since it is possible to have larger deviations below the mean than above. But even if we assume a normal curve, his corrected values of a mean of 41.2 weeks and a standard deviation of 12 days will not lead to 1/8 of the distribution falling before 40 weeks, but gives 24% of the total as occurring before 40 weeks. Perhaps Dr. Doyne Bell omitted to express the deviation from the mean in terms of the standard deviation when entering the tables of the probability integral.—We are, etc.,

W. T. RUSSELL.
London School of Hygiene and Tropical Medicine. W. J. MARTIN.

Ligature of the Innominate Artery

SIR,—Sir W. I. de Courcy Wheeler has asked me to put details of this case on record on the grounds that only about seventy have been reported, though there must be many more unpublished.

A woman of 67 came to the Leicester Royal Infirmary on account of a swelling above the right clavicle; this had been first noticed six months before. The right arm had recently felt dead and its power was diminishing. On examination there was an expansile swelling above and behind the middle of the right clavicle; the right hand showed clubbing of the fingers and slight wasting of the intrinsic muscles compared with the opposite side. The grip was impaired on the right; there was no delay in transmission of the right radial pulse; the reflexes in both upper limbs were normal. Pupils reacted to accommodation but only sluggishly to light. Knee-jerks were absent. There were clean-cut ulcers with yellowish bases on the inner and lower parts of both tibiae. Wassermann reaction ++; Kahn reaction ++++. *X*-ray examination of right shoulder girdle showed no bony change.

Operation, May 24, 1940: Incision along line of lower part of sternomastoid, out along clavicle, and down upper part of delto-pectoral groove; lower ends of right sternomastoid, sternohyoid, and sternothyroid detached temporarily; middle third of clavicle divided. Aneurysm of the innominate artery extending into the beginning of the subclavian; scalenus anterior and part of brachial plexus thinned out over aneurysm. Innominate artery ligatured, and pulsation in aneurysm immediately stopped; tributaries of sac ligatured; three-quarters of sac excised and remainder oversewn; no drainage.

Post-operative course: Middle third of clavicle failed to unite; wound otherwise healed soundly. No signs of cerebral damage appeared at any time; no pulsation or thrill recorded in the aneurysmal site; pain in the arm persisted but was lessened; some diminished power of grip persisted in the right hand.

—I am, etc.,

Leicester. DONALD MCGAVIN.

Pleurisy and Pleural Effusion

SIR,—From the observation post at the Pleural Effusion Unit established by the L.C.C. at Queen Mary's Hospital, Sidcup, I wish to make a few comments on Wing Cmdr. R. R. Trail's very welcome article (Jan. 23, p. 98). The subject of pleurisy and pleural effusion is becoming more important, not only because of the increase in the number of cases concomitant with the general increase in tuberculosis, but also because idiopathic and secondary tuberculous pleural effusion appears to follow a more serious course than it used to, probably owing to the lowered general resistance of the average patient in wartime.

The importance of correct appreciation of the symptom pain is rightly stressed by Wing Cmdr. Trail; I would like to add that pain on laughing and on yawning can be an early symptom of pleurisy, just as it is one of the last to disappear.

In the differential diagnosis no mention is made of rheumatic pleural effusion, which can present some difficulties. I think mention should be made also of the so-called sulphapyridine effusion, as this term is starting to creep into medical language. Pleural effusion due to the action of sulphonamides does not exist; it has never been reported in the course of treatment of non-pulmonary conditions by these drugs. It is possible, though difficult to prove, that chemotherapy has caused an increase in the number of metapneumonic serous effusions, as some of these effusions would have become purulent in pre-chemotherapeutic days; that is all. It must be admitted that the differential diagnosis between pleural effusion and pneumonia with effusion can be difficult, some cases of primary effusion look really ill and are profoundly toxic, and have not "the appealing look, the clear complexion, and the bright eye of the average tuberculous patient." The great value of a white cell count can be offset, if not resorted to early, by the depressant effect on the leucocytes of sulphapyridine, which is nowadays frequently administered blindly.

We attach much significance here for the diagnosis *a posteriori* of tuberculous pleural effusion to the finding in the radiograph of grossly enlarged and fluffy hilar glands, frequently more conspicuous on the opposite side to the effusion. The persistence of these shadows three months or more after the onset of the effusion appears to be of fairly serious prognostic significance. It is, of course, a wise precaution to perform a tuberculin skin test in every case in which the tubercle bacillus has not been demonstrated.

Few people will agree with Wing Cmdr. Trail's statement that "the radiograph of the transudates of cardiac and renal failure generally shows bilateral effusion, small in extent, and confined to the costo-phrenic angles." In congestive heart failure the effusion is often of considerable size, and is much larger on the right side. To distinguish between a transudate and an exudate at the bedside, Rivalta's test can be of real aid; one or two minims of the fluid to be examined are dropped into a glass container filled with 1:100 acetic acid; a smoky cloudiness is observed on the downward path of the fluid (owing to its high protein content) if it is an exudate. When, after other suitable investigations, doubt persists as to the nature of the effusion, whether it be an exudate or a transudate, it may be useful to recall that an exudate has a lower *p*H than that of the patient's blood, while the *p*H of a transudate equals that of the blood.—I am, etc.,

E. MONTUSCHI.

Peptic Ulcer a Deficiency Disease?

SIR,—The gastric and duodenal ulcers of to-day seem to possess some of the characteristics of deficiency ulcers—i.e., their chronicity, their resistance to treatment, their tendency to rapid perforation and haemorrhage.

The gastric and duodenal ulcers in my practice have responded in a most hopeful way to vitamin therapy. Two tablets of a well-known vitamin preparation containing in each 2,500 I.U. of vitamin A, 160 I.U. of B_1, 250 I.U. of C, and 250 I.U. of D given three times a day relieve all pain and discomfort in 6 to 10 days. Then a maintenance dose of two tablets per day seems to keep patients symptom-free—for how long I cannot yet say.

One patient was eight weeks at a base hospital with his ulcer not healed. Because of financial stress he discharged himself and went back to work. Three weeks later an *x*-ray film revealed a penetrating ulcer. He was on the point of being admitted to hospital for a partial gastrectomy when he developed a quinsy. I began to give him the above vitamin preparation—6 tablets a day. He was free from pain in 6 days, and was then able to sleep all night without pain waking him at 4.30 every morning. Of his own accord he gave up his two-hourly feeds. Another patient, whose duodenal ulcer was responding to the vitamin treatment, developed a corneal ulcer for the second time—probably a B_2 deficiency. This is interesting because of the well-known relation of corneal ulcer to vitamin A deficiency.

I have twenty-odd ulcer patients on vitamin therapy and am keeping notes. Neither rest in bed nor diet restrictions seem to be essential, nor alkaline powder.

All this may be coincidence, but my clinical experience suggests that peptic ulcers are a manifestation of vitamin deficiency disease. Nearly all vitamin foods are rationed, or are on points or in short supply—milk, butter, eggs, meat, fruit, and green vegetables (last winter).

This must be what happened in Denmark in 1917-18. Meulengracht's haematemesis diet was, in Denmark, successful because it was a way of introducing vitamins.—I am, etc.,

London, S.E.18. J. J. O'MULLANE.

"Calorie Control" Diabetic Diet

SIR,—I have read the article by Dr. A. C. Crooke and Miss Ella Scott (Jan. 16, p. 64) and Dr. R. D. Lawrence's reply (Jan. 30, p. 143) with considerable interest. Is not the difference of opinion due to the fact that no attempt has been made to differentiate the types of diabetes? Physiology shows that a glycosuria may arise from many different causes, and my own experience in the treatment of patients is in agreement with this. So long as all cases in which there is sugar in the urine together with a high blood sugar are labelled as diabetics, we shall be able to point to success and failure with many varieties of treatment.

Experience before the introduction of insulin may be helpful. Some of us remember the starvation treatment of Allen and the high-fat treatment of Newburgh and Marsh, each of which gave excellent results in certain cases. Two instances in my own experience show how differently patients may respond to different methods. Nearly 20 years ago a jam manufacturer consulted me, and I found a moderate degree of glycosuria with a raised blood sugar. After I had prescribed an appropriate diet he told me that he would follow it, but that he had eaten jam in large quantities all his life and would continue to do so. I told him that he would kill himself. Ten years later I saw him again with a normal urine and blood sugar. He told me that he had kept to the diet together with jam in large quantities. Five years later I was called to see him in a moribund condition with gangrene of the leg, acetonuria, and a high blood sugar. In contrast to this, a young girl on the verge of coma with intense ketosis and a high blood sugar was given nothing for five days but fat in the form of cod-liver oil. The ketosis disappeared, she made a good recovery, and lived for some years on a restricted diet. Metabolic rest, despite the alleged ketone-producing capacity of fat, was sufficient to produce stabilization. The first case was probably one of arteriosclerosis accompanied by glycosuria; the second, a true pancreatic diabetes.

Are not many of the cases we see, in which large doses of insulin fail to produce a permanently normal urine and blood sugar, due to a factor other than the pancreas which has not been recognized? In a normal person the blood sugar will be lowered by insulin and may produce toxic effects. The same may happen in a diabetic if the cause is other than pancreatic. For this reason I agree with Dr. Lawrence that the doses of insulin advocated are high and might lead to unpleasant results.—I am, etc.,

Manchester. T. H. OLIVER.

SIR,—Without entering into a discussion of the physiological basis of diabetic diets we have one criticism of Dr. A. C. Crooke's system (Jan. 16, p. 64). In Birmingham most of the younger men are working long hours, often at arduous tasks, and in many cases have a number of their meals at work. Of the remainder, who may be presumed to have time to make a hobby of their ailment, very few have either the temperament or the good sense to co-operate in any but the simplest dieting. If the accurate weighing suggested by Dr. Crooke were ordered for these patients they either could not or would not co-operate for any length of time. In our experience the factors that lead to success in diabetes are courage, good sense, and a diet of good quality. These things are more important than facility in shallow arithmetic.—We are, etc.,

GERALD KNIGHT.
Birmingham J. M. MALINS.

Anaesthesia for Laryngofissure

SIR,—I fear that Dr. C. B. Lewis in his most valuable medical memorandum (Feb. 6, p. 162) has overlooked one danger of trilene. He points out that in this operation the diathermy is safe because trilene is non-inflammable. Trilene is merely trichlorethylene stabilized with thymol. Trichlorethylene decomposes at 125° C. into hydrochloric acid and the deadly phosgene gas.—I am, etc.,

London, W.2 THOMAS E. A. STOWELL, F.R.C.S.

Coarctation of the Aorta as an Obstetrical Complication

SIR,—After reading Dr. C. W. Walker's interesting contribution on coarctation of the aorta as an obstetrical complication (Feb. 13, p. 190) I feel that it would be of general interest to add a case that occurred in my own practice in Shanghai during the last war.

An Englishwoman, 23 years of age and recently married, whom I had never seen before, asked me to attend her in her first confinement. At the pre-natal examination I found her to be a very finely developed and well-balanced young woman. I learned she was a keen tennis player, of an active and self-reliant nature, and had hardly had a day's illness in her life. She had no trouble whatever during pregnancy, and elected to remain in her own flat for the confinement rather than go to a nursing home.

The early stages of labour were borne quite cheerfully, and when I returned later I found her sitting up and very hopeful. I moved into an adjacent room to read for a while when I was suddenly called back by the nurse to find that the patient had fainted whilst being helped on to the couch. I found her unconscious, very pale, and with a small irregular pulse, the rate being 120. Within a few minutes consciousness returned, the pulse rate dropped to 90, and she seemed almost her normal self again, though the pallor remained. Sensing danger ahead I telephoned an ambulance and, after half an hour's rest, took her to the nursing home, where my fears were soon allayed. She passed through the final stages of labour with perfect equanimity, and within two hours a female child weighing 8 lb. was born without undue distress.

On the following morning I found that the mother had slept well and was comfortable, though the pulse rate had kept at 100–110 since her confinement. At five o'clock in the afternoon I called again to find her happy and content, having rested well during the day; the pulse rate was unchanged. I had hardly passed into the hall when I was called back to find the mother dead.

At the post-mortem examination the pericardium was distended with fluid blood. There was no obvious enlargement of the heart, though the muscular development of the left ventricle was well marked. The sheath of the aorta was distended with dark blood clot, and there was a longitudinal rupture of the vessel one-third of an inch in length on the left side just above the valves. The walls of the aorta were perhaps thinner than normal but otherwise appeared normal. Below the origin of the left subclavian artery there was complete coarctation of the aorta, hardly allowing the passage of a bristle. The post-mortem findings pointed almost conclusively to the aortic rupture having occurred when the patient first fainted; a dissecting aneurysm formed in which the blood clot strengthened the wall sufficiently to allow the circulation to proceed, which it did for 17 hours; then the outer wall of this aneurysm gave way and the pericardium was instantly flooded.

—I am, etc.,

Guildford. W. B. BILLINGHURST.

Preparation of the Hands for Operation

SIR,—A very interesting method of preparing the hands was quoted from Davletov, a Russian surgeon, in the *Bulletin of War Medicine*, Jan., 1942 (p. 169), regarding a series of 200 cases, and I am surprised that the idea does not seem to be widely known or applied. Starting from the fact that most pathogenic bacteria require an alkaline medium (*p*H 7.5 to 8.0), that the reaction of the skin changes from strongly acid to strongly alkaline between the surface and the basal layers (*Lancet*, 1942, **2**, 18), and that artificial gastric juice without pepsin is bactericidal and does not harm the tissues, he proceeded to try the effect of washing his hands, which were contaminated with staphylococci, streptococci, and diplococci, with gastric juice and with dilute hydrochloric acid alone.

He finally developed the technique of washing his hands for two periods of 5 minutes in 0.1% HCl with the aid of a piece of sterile cotton-wool, and then wiping his hands for 2 to 3 minutes with 0.15% HCl in 20 to 40% surgical spirit. The results were excellent. The method requires no preliminary scrubbing, no sterile water, and no subsequent application of mercuric perchloride or iodine.

This appears to be a simple, cheap—one may almost state physiological—way of preparing the hands, and should materially help to remedy the dearth of rubber gloves which threatens us at the present time.—I am, etc.,

St. Mary's Hospital Medical School, W 2 LEON RADCLYFFE.

Absenteeism in Industry

SIR,—Absenteeism in industry is a problem facing both lay managements and medical practitioners and through them the whole nation. Granted that much of this absenteeism is due to genuine organic disease or disablement, a not inconsiderable proportion is due to a type of incapacity, variously labelled by the profession as assorted "catarrhs," pleurodynia, dyspepsia, or, more commonly, "debility," nervous or otherwise.

As an industrial medical officer in the full-time service of a concern whose product is of vital importance to the war effort, I receive many and various certificates sent in by absent employees. Having been a G.P. myself for many years I am fully acquainted with the problems facing my erstwhile colleagues. I am now entering a plea that they should consider those which face me and other industrial M.O.s, the first of which is to maintain our loyalty to our professional brethren in the interpretation to managers of the certificates sent in by them to explain a worker's absence from essential duty. One's professional solidarity is on occasion strained to the utmost, as, for instance, when a batch of "dyspepsias" arrives to cover the day or two succeeding New Year's Eve. Certificates in industry nowadays are as vitally important to the community (with a corresponding responsibility on those who issue them) as are death certificates, where lax or undesirable terms are defined in a schedule. By a similar schedule can we help ourselves to obviate the refined form of blackmail to which we are subjected by the certificate hunters?

May I beg from some leader of our profession a definition of the diagnosis "nervous debility," which, as I understand it to mean at present, is a syndrome characterized subjectively by a dislike of the job in hand and objectively by a desire on the part of the practitioner to get rid of a neurotic. What reliance can the average intelligent manager put on the certificate of a doctor who states that his patient is unfit to work in the conditions of a certain factory twenty-five miles away, when, apart from the uncorroborated evidence of the patient, it is obvious that he can have no knowledge of what those conditions are? Many of these medical euphemisms for "absent from duty" just won't wash nowadays with managers who are harassed by queries about production. Comparisons between workers at home and Service personnel are invited and are hard to counter. I am convinced that our profession is being imposed upon now that, in these days of industrial conscription, "the doctor" is the last resort of the "work-shy." I believe that the remedy is in our own hands—more "austerity in certification."—I am, etc.,

A. G. EDDISON.

Treatment of Bacillary Dysentery

SIR,—In a letter on this subject Flight Lieut. A. G. McManis and Major W. Gordon Rich (Jan. 16, p. 82) mention good results with sulphapyridine. In the Middle East sulphanilamide, sulphapyridine, and sulphaguanidine have all been used, and the results obtained with the last-named drug in one general hospital on the first 76 cases so treated are given in a paper by Bulmer and Priest in the *J. R.A.M.C.* of December, 1942. As we had no opportunity to correct the proofs a number of misprints have unfortunately crept in, but we summarized the position by the statement that sulphaguanidine was found to be, in the admittedly small series of cases, as specific for bacillary dysentery as sulphapyridine was, for example, in pneumonia. In this first series no toxic effects were encountered; in a later and larger series there were a few cases of rubelliform rash, unaccompanied by other ill effects, about the fifth day of treatment, and one case of haematuria with pain, similar to that which occurs with sulphapyridine but mild in degree and of short duration.

We have also tried sulphanilamide and sulphapyridine for bacillary dysentery. The former we found of little value. With the latter good results were obtained, which in some cases could be described as dramatic. We considered, however, that of the drugs of this series then available sulphaguanidine remained the treatment of choice, since toxic effects are rare, and it does not produce anorexia, nausea, and depression, which were common with sulphapyridine; the patient under treatment with the former was a more cheerful and fitter man.—I am, etc.,

W. M. PRIEST.

Cardiac Invalidism in Children

SIR,—Referring to Dr. R. P. Garrow's letter (Jan. 23, p. 114), I cannot share his despondency and alarm in regard to the work of cardiac centres. In particular I take exception to his opinion that attendance thereat is liable to confirm the invalid attitude of both child and mother. In addition to its obvious functions in the investigation, diagnosis, and supervision of suspected and actual cases of rheumatism and cardiac disease, a properly conducted clinic should lessen the period of real and bogus cardiac invalidity. Such a clinic certainly cannot initiate or perpetuate unfounded fears, but rather dispel them.

Reviewing the work of my council's rheumatism and cardiac clinic during the past year, it is found that the majority of cases were referred from hospitals, school clinics, or by general practitioners, with definite symptoms and/or signs indicative of congenital or acquired cardiac or rheumatic disease. In only an insignificant number of cases could a child's attendance be ascribed to maternal over-anxiety such as Dr. Garrow describes, and in these instances the attendance resulted in the effectual dispelling of the unjustified fears.

I consider that a properly organized and competently staffed rheumatism and cardiac clinic working as an integral part of a similarly constituted public health service performs most valuable work in the abolition of both preventable and unwarranted cardiac invalidism. In such circumstances I lack Dr. Garrow's temerity in uttering *ex cathedra* pronouncements on the findings of a rheumatism or cardiac specialist, and I am constrained to inquire what especial qualifications he possesses to justify such oracular declarations.—I am, etc.,

A. H. G. BURTON,
Medical Officer of Health.

Ilford.

Obituary

H. W. C. AUSTEN, M.D., L.D.S.ENG.

Harold Austen, who died from pneumonia on Jan. 22, was born at Ramsgate in 1868, the eldest child of Josiah Austen, a staff surgeon in the Royal Navy. He was educated at Tonbridge School and St. Bartholomew's Hospital, qualifying M.B., B.S. in 1890. He took the M.D.Lond. in 1892 and the L.D.S.Eng. in 1897. After qualifying he was house-physician to Dr. (later Sir) William Church, clinical assistant to the Central London Ophthalmic Hospital, and assistant medical officer to the Western Hospital, Fulham. In 1901 he was appointed assistant dental surgeon to the Royal Dental Hospital and the following year to St. Bartholomew's Hospital. For ten years he lectured on materia medica at the Royal Dental Hospital, and was the first to hold this lectureship. In 1902 he edited, with Douglas Gabell, a materia medica for dentists, which has since reached a seventh edition. During the last war Austen joined the Royal Naval Volunteer Reserve; he was engaged chiefly in telegraphy on the East Coast of England and was frequently entrusted with carrying important dispatches to London. In 1917 he married Juliette Mazet, who survives him. On retiring from the staff of Bart's in 1928 he was elected a governor and a consulting dental surgeon to the hospital. He had been a member of the B.M.A. since 1891.

Austen was fortunate in having a large number of interests, in many of which he excelled, notably in music. Membership of the Society for Psychical Research and other societies, painting, a good knowledge of ceramics, and gardening afforded him other pleasures. Having the instinct of the perpetual student he took up the study of Chinese in later years. A man with all these attainments was naturally a bibliophile, and he had collected a very fair library. It was, no doubt, largely owing to his many outside interests that he took up dentistry to allow him further scope and opportunity for indulging in these recreations.

Harold Austen was a lovable character, quiet, unassuming, devoid of all conceit and boastfulness, and possessed of good common sense. He never experienced failure in any of his examinations, and if he had had a little more thrust, and perhaps been a little less concerned with his outside attainments, he would have made a more prominent name in the medical world. Possibly this would have been at the expense of his endearing personality. Austen is survived by two brothers—one in Auckland, New Zealand, and the other a retired Commander in the Royal Navy—and a sister, Winifred Austen (Mrs. Frick), a well-known painter and etcher of animal and bird life. F. C.

Mr. EDWARD BUTTAR writes: Harold Austen had an uncommon capacity for esteeming "other better than himself." So it was entirely in keeping that he should have studied Chinese in his later years; for the ceremonial self-depreciation of the ancient Chinese was entirely in accordance with his own genuine attitude. Loyal in affection, he bestowed that affection so wholeheartedly that it was difficult at times to feel worthy of such friendship. His secret, beyond doubt, lay in his conviction that the world is full of all sorts of interesting matter and in his determination to have his full share of it. To many he may have seemed a shy and even slightly embarrassed man, but, when offered a box on which his match would strike, he at once appeared as an exponent of the now almost lost art of conversation. In the words of Joseph Conrad, ". . . the sort that's always chasing some notion or other round and round his head just for the fun of the thing." His was indeed a happy life.

JAMES MURRAY, M.A., M.D.

The death occurred on Feb. 2 at Inverness at the age of 90 of Dr. James Murray, well known in the North of Scotland as a skilful practitioner, a wise and purposeful administrator, and a genial personality. He was Highland born and bred, being a Murray of Kilcoy in the Black Isle, and a genuine and loyal Highlander he remained. Educated at the Inverness Royal Academy, where he did well and began his career as a medallist, he went at the early age of 15 to Edinburgh University. After taking his M.A. he studied medicine, and when a student in Lord Lister's class was awarded the medal for clinical surgery. He qualified M.B., C.M. in 1876, and then served for a time as house-surgeon at the Royal Infirmary in charge of Patrick Heron Watson's wards, and under his tutelage Murray must have acquired his distinct surgical bent. There followed a short period in a coastal town in Scotland, but the call of the Highlands, his "ain countrie," was strong in him, and in 1879 he went north to his beloved Inverness, there to practise for sixty-odd years among the Highland folk he loved. For the whole of his professional life in Inverness he was connected with the Royal Northern Infirmary, first on the staff and then on the board of management. The Infirmary and its welfare occupied much of his care and attention in season and out. While at the Annual Meeting of the B.M.A. at Oxford he gained the ear of Lord Nuffield and received at once a cheque for £1,000 towards the extension of the Infirmary which was then going on. Next to the claims of the hospital came those of the B.M.A., for he was a member for 64 years, served on the Central Council in 1900-1 and again in 1906-7, and for 22 years was Representative of the Inverness Branch at the A.R.M.

Dr. Murray was a good mixer, making friends easily and being ready to discuss any subject, especially in music, literature, or painting. He disliked the motor car, and was a great believer in the healthy exercise afforded by cycling; he continued to make his visits on a bicycle until he was over 80. James Murray was a typical Highland gentleman, courteous, cultured, kindly to everyone, and punctilious in the discharge of all his engagements. The funeral service at the Old High Church, in which he had for many years been the senior elder, was indicative of the esteem in which he was held by all classes of the community. He was predeceased by his wife, and leaves two daughters, one of them being the Warden of University Hall, St. Andrews.

H. LAMBERT LACK, F.R.C.S.

Consulting Aural Surgeon, London Hospital

We regret to announce the death on Feb. 14, in his 76th year, of Mr. Harry Lambert Lack. He was born in 1867 and was educated at King's College, London, qualifying M.R.C.S., L.R.C.P. in 1890 and taking the M.B. of the University of London in 1892. He was elected F.R.C.S. in 1893 and proceeded M.D. in the following year. When the B.M.A. met at Ipswich in 1900 he acted as secretary of the Section of Laryngology and Otology, was vice-president of the same section at Oxford in 1904, and at the Aberdeen Meeting in 1914 held office as president of the Section of Laryngology, Rhinology, and Otology.

A colleague writes: Lambert Lack was one of the most distinguished rhino-laryngologists of our time. Many important contributions resulted from his original outlook and aptitude for research. He received his medical education at King's College Hospital, but during the greater part of his professional career he was associated with the London Hospital. He owed much to a sound training in surgery and pathology; the latter subject was always of special interest to him, and his opinion on a microscopical specimen was valued by many who had made pathology their life study. He was awarded the Jacksonian prize in 1899 for an essay on "The Pathology, Diagnosis, and Treatment of Inflammatory Affections of the Nasal Fossae and the Associated Sinuses and Air-cells." This essay was subsequently revised, chapters were added, and a book, *The Diseases of the Nose and its Accessory Sinuses*, published in 1906, was the result. This was the first really scientific and exhaustive treatise on the subject to appear in English, and the opinions of leading specialists are fully reviewed and analysed. The book is especially valuable for the amount of original material which it contains, much of which resulted from pathological studies carried out by the author. The sections on nasal obstruction and sinusitis are quite exceptional. Subsequent contributions appeared from time to time dealing with subjects connected with the nose and throat, all of great merit. Lack was never redundant in words written or spoken, and he had the capacity of lucid and masterly exposition. He was much beloved by his colleagues, and the author of this short appreciation learned to value his extreme modesty, never-failing kindness, and stimulating personality. He treated patients at the

London Hospital with the same courtesy and care as those who came to consult him privately.

Lack had many other interests outside his strictly professional activities. He loved beautiful things, and a good deal of his spare time was spent in the acquisition of a choice collection of furniture. He was extremely fond of the country, and at one time, when he had a week-end house at Littlestone, he was an enthusiastic golfer. He had a great knowledge of literature and poetry. Mrs. Lack, who survives him, shared his literary tastes, and the "Poetry Society," which met at his house and in which his talented wife took a distinguished part, was a source of enjoyment to many of his friends. Three sons and a daughter also survive him.

Dr. **Constance Elizabeth Ridout** died on Jan. 19, to the great regret of all who knew her. Her health began to fail last August, but with characteristic courage and resolution she continued in active practice until three days before her death. She started work in the literary world, but the last war opened her eyes to the sufferings of humanity and she determined to take up medicine. She was a student of University College and qualified M.R.C.S., L.R.C.P. in 1922. Her first post was with the late Mr. J. Russell Howard in his surgical out-patient department at the London Hospital, where later she became clinical assistant in the genito-urinary department (women). In 1924 she came to Oxford as R.M.O. at the Wingfield-Morris Orthopaedic Hospital. Later Dr. Dorothy Crook was appointed house-surgeon to the hospital, and thus there began a professional association and a close friendship which was never interrupted, for in 1926 she and Dr. Crook started in general practice together in Oxford, and here they have lived and worked together in the highest tradition of our profession. Since 1933 Dr. Ridout had been clinical assistant at the genito-urinary department (women) at the Radcliffe Infirmary, and since 1937 had worked for the Oxfordshire County Council on ante-natal, maternity, and post-natal care in the country round Oxford. When the war came she undertook the work of medical officer to the hostel for evacuated children in Oxford.

She saw her work generously in the way of the old-fashioned doctor, caring for her patients as individuals and family groups, much interested in the maintenance of health of mind and body and in the prevention of disease and deformity. She was a woman of independence of mind, of remarkable and rare personality. To those of her colleagues and patients who knew her well she was a true and attractive friend of unusual character.—G. R. G.

The Services

The King has approved the award of the R.N.V.R. Officers' Decoration to Surg. Cmdr. W. McO. MacGregor, O.B.E., and Acting Surg. Cmdrs. W. F. Lascelles and H. G. Ungley, R.N.V.R.

Surg. Lieut.-Cmdr. W. H. C. M. Hamilton, R.N., has been mentioned in dispatches for services in convoys to North Russia.

CASUALTIES IN THE MEDICAL SERVICES

Prisoner of War.—Lieut. J. G. McGavin, R.A.M.C.

Missing.—Wing Cmdr. D. Magrath, R.A.F.

Missing (Unofficially reported Wounded and Prisoner of War).—Capt. S. D. Corry, R.A.M.C.

DEATHS IN THE SERVICES

Lieut.-Col. **Lessel Philip Stephen**, I.M.S. (ret.), who died at Grimsby on Feb. 1, was born on July 20, 1874, and was educated at the University of Aberdeen, where he graduated M.A. in 1895 and M.B., Ch.B. (with distinction) in 1899. He took the D.P.H.Lond. and the D.T.M.&H.Camb. in 1907, and was elected F.R.C.S.Ed. in 1912. He entered the I.M.S. as lieut. soon after qualification, was promoted capt. in 1903, major in 1911, lieut.-col. in 1919, and retired in 1926. Among the posts he held while in India were those of acting professor of ophthalmology and ophthalmic surgeon in the Medical College, Bombay, and superintendent of the Medical School and civil surgeon, Hyderabad, Sind. After retiring from the I.M.S. he settled in Grimsby and was honorary surgeon to the hospitals at Horncastle, Scunthorpe, and Louth, and surgeon to Brigg Infirmary. He was also ophthalmologist under the Ophthalmic Benefit Scheme and consultant under the Public Health (Notification) Puerperal Fever and Puerperal Pyrexia Regulations, 1926. He had been a member of the B.M.A. since 1903 and was chairman of the Grimsby Division in 1935–6.

Medical Notes in Parliament

Beveridge Report in the House of Lords

When the House of Lords on Feb. 24 discussed the Beveridge report Viscount Samuel said it constituted the finest body of proposals on social reform which had been presented to the country in our time. There was no reason for postponing all preparations until they knew exactly what the financial situation would be after the war. Archbishop Lord Lang could not conceive that the Government, having gone so far, did not feel themselves bound to go further. He maintained that the appointment now of a Minister of Social Security was analogous to the appointment of a Minister of Town and Country Planning. There was a great deal that such a Minister could do at present.

Medical Provisions

Lord Dawson said that in the debate in the House of Commons family allowances and the hospital and health services had been pushed to the front and had been blessed by three Ministers of the Crown. He was sure that had resulted in great activity within the Ministry of Health. It seemed necessary, therefore, to make some statement to show where the medical profession stood. Sir William Beveridge, although stating in Assumption B that the medical services would take an important place in his plan, avoided saying what the scheme for those services should be. Sir William assumed that, "from the standpoint of social security, a health service providing full preventive and curative treatment of every kind to every citizen without exceptions, without remuneration limit and without an economic barrier at any point to delay recourse to it, was the ideal plan." That assumption, Lord Dawson continued, had been considered by the medical profession for many years. After the last war Lord Addison instituted an inquiry into the medical services, and that inquiry, of which he (Lord Dawson) was chairman, reported that changes were necessary, because the organization of medicine had become insufficient and because it failed to bring the best means of maintaining health and curing disease to all citizens. That had been adopted unanimously but was left in abeyance.

During the past two years the medical profession had studied the replanning of medical services. The Medical Planning Commission under the aegis of the B.M.A. and the Royal Colleges, with representatives of municipal doctors, private practitioners, men interested in preventive and curative medicine, had reached a remarkable degree of agreement. At Oxford a medical organization had behind it Sir Farquhar Buzzard, Lord Nuffield, and Sir William Goodenough. A third body, consisting of King Edward VII Hospital Fund and the Voluntary Hospitals Association, had also studied this question, and so far the agreement was substantial. The present Minister of Health and his medical officers had met these efforts in an excellent spirit. The ideal assumed by Sir William Beveridge was one which was seldom attained in one stroke. But there had seemed to be in the House of Commons during the previous week an idea that only about six weeks was required to transform the practice of medicine. Lord Dawson suggested that they should go step by step, should do it by agreement between the two parties, and should show both patience and statesmanship. Medical practice, as regards both doctors and patients, was contained in customs fixed firmly in the habits of the people, involving not only their reason, but their emotions and their feelings.

Problems Needing Action Now

Certain matters had been ready for tackling for a considerable time. The first was the bridging of the gap in theory and in practice between preventive and curative medicine. The detachment of these two had been to the disadvantage of each branch and to the public service. Hospital practice and general practice must comprise the care of people's health and the furtherance of health as their chief objective. Medical officers of health must come out of their obscurity, come on to the staffs of the hospitals and meet their colleagues regularly. They had to alter medical education so that the student from his early days was taught that the building up of health must take precedence of the cure of illness.

The second matter which could be dealt with now was to make the practice of medicine increasingly institutional. Medical practice was based on a growing number of sciences, and in its search for truth required team-work. Team-work required equipment, and teams were better situated side by side in a building equipped for the purpose. Team-work was a necessity if only for economy of man-power and economy of cost. Once that was admitted, institutional provision must increase. Two instances had a very promising future. In the provision of health centres in industrial organizations there was a vast future for useful work. There the principle was that of putting the practice where people assembled in groups. The promotion of child health also lent itself to immediate action. It should take precedence of almost every medical movement at this moment. There were schemes of health, notably in London, which stood forth as an example, a scheme in which the leading voluntary hospital for children's diseases would join hands with the Post-graduate Medical School, which would undertake the maternity end in the pre-natal clinics. In that movement not only voluntary associations but the municipal organizations of London would share, and he had confidence that the scheme would be copied in other parts of the country.

What he had said implied a pattern of hospitals, health centres, and clinics allotted to each area. They must be of various grades, according to the needs of the population and distributed where most needed. The areas of distribution must be large, but not too large, and if they were going to serve their purpose we must include several major local authorities. A small area could not have an adequate service, or could only have it at excessive cost. At the head of each region there would be a key hospital, and wherever possible that key hospital would be a teaching hospital. These hospitals would consist in part of local authority hospitals and in part of voluntary hospitals.

Self-determination for the Profession

But a service of this description could not be constructed except under the skilled guidance of the medical profession. Medicine became every year a more complex art based on an increasing number of sciences. It was idle to think that any scheme of hospital service could be run unless a vocational body was always ready at hand to give advice to the administrative authority. The latter must have the last word, but it required the vocational body to advise before it took the final decision. It was not to be expected that a great profession was going to be moved about and take its orders from laymen. Under the agreed control of Parliament the medical profession would demand self-determination in the same way as the Bench, the Bar, and the Church looked after their affairs without let or hindrance. Just as the medical profession was taking a prime responsibility in putting forward these proposals, so it would expect to take an equal part in their guidance. The medical profession had the difficulty that in order to do good planning they must, while having collectivism, have 100% individualism in personal relations.

Government's Reply

Lord SIMON said it was grotesque to talk about the Government showing only a dilatory and half-hearted interest in the subject. Among problems of the post-war period that of health was only a portion of what must be written down as post-war requirements which could not be denied. On the proposal of universal State services, the Government had said, two months from the issue of the report: "We endorse that and we will work for it"; was that a half-hearted adherence? The Government had every intention of making good this immense proposition with the co-operation of those who could advise them best. The Government conceived the scheme not as one which would automatically end a medical man's private practice and not as a scheme in which the voluntary hospitals would have nothing to do. On the contrary, they could continue and they would have their part to play. Sir William Beveridge had said that unless a universal public health service were secured, the proposals he made had no meaning, but he did not say (because it was not his business to say) how this service was to be secured. The comprehensive medical service, the principle of which was accepted, involved bringing in hospital services, institutional services, the part which the local authorities should play, and discussion and negotiation with the doctors and with the doctors' representative organizations. The whole of that subject was in the grasp of the Minister of Health in England and the Health Department in Scotland. To transfer it to someone else and call him Minister of Social Security would not save time.

Recruitment and Distribution of Nurses

In reply to Miss Ward on Feb. 11 Mr. BEVIN said the present shortage and uneven distribution of nurses and midwives for civilian work demanded special measures. After consultation with the organizations representing the interested parties, and in agreement with the Minister of Health and the Secretary of State for Scotland, he had decided to appoint a National Advisory Council for the Recruitment and Distribution of Nurses and Midwives to advise on all questions relating to the recruitment and distribution of male and female nurses and of midwives on civilian work. The council, which would be presided over by a Parliamentary Secretary to his Ministry, and with which officers of the Departments concerned would be associated, would consist of representatives nominated by the various organizations concerned. He would ask the council to meet at an early date and to consider immediately the measures for increasing recruitment, the arrangements for a special registration of nurses and midwives, and the priority to be accorded to the different demands for the different types of nurses and midwives, as well as make suggestions for easing the situation of certain types of hospitals with large immediate demands, such as tuberculosis and mental institutions. There was no intention of changing existing arrangements where these were working satisfactorily. The administration of measures decided upon would be entrusted to the appointments department of his Ministry, acting where necessary through the local appointments offices, each of which would be assisted in its work by a local advisory committee.

Milk Supply and Tuberculosis

Mr. MABANE, replying on Feb. 17 to Major York, said that in March, 1942, out of a total supply by wholesale producers of 3,880,000 gallons of tuberculin-tested milk, approximately 3,000,000 gallons were sold to buyers on the same terms as ordinary milk. It was probable that most of this was bulked with ordinary milk before sale to the consumer. Lord Woolton was considering whether means could be devised both to encourage the future production and consumption of tuberculin-tested milk and to raise the general standard of the milk supply of the country. Mr. Mabane had no reason to think that pasteurization of tuberculin-tested milk would affect the future production of such milk.

Sir CHARLES EDWARDS drew attention on Feb. 17 to a statement by the chairman of the Glamorgan C.C. Diseases of Animals Committee that unless there was an improvement in the condition of the milk public authorities should stop the distribution to children as a means of stopping the spread of tuberculosis. Miss HORSBRUGH said she had seen a Press report of the statement mentioned. In the majority of cases tuberculosis due to bovine infection was non-pulmonary; at all ages it constituted about 30% only of the cases of non-pulmonary tuberculosis. The incidence of non-pulmonary tuberculosis in children under 11 in Wales gradually declined up to 1937, but began to rise in 1938. The increase was rather more marked in 1940, the year in which the national milk scheme was introduced. The numbers of cases notified in the years 1940 and 1941 were 388 and 389, an increase of 16% compared with 1939 and of about 12½% compared with the average for the years 1933 to 1939. Lord Woolton had under consideration practical steps to secure the elimination of active tuberculosis germs from liquid milk.

Investigation of Growth Rates among School Children.—A few local education authorities have continued periodical weighing and measuring of children during the war, and a scientific investigation into growth rates in certain neutral and evacuation areas is being undertaken on behalf of the Board of Education. This investigation, so far as it goes, shows that since the beginning of the war growth rates measured by height and weight are being well maintained.

Notes in Brief

The number of chairmen of medical boards is at present 180. The amount paid in fees to consultants and specialists during the period Sept. 1, 1939, to Dec. 31, 1942, was £395,500.

Medical News

A meeting of the London Association of the Medical Women's Federation will be held at B.M.A. House, Tavistock Square, W.C., on Saturday, March 13, at 3 p.m., when the possible changes in medical practice as envisaged in the Beveridge report will be discussed, and Dr. Kate Harrower, Glasgow M.W.F. representative on the B.M.A. Insurance Acts Committee, will present a memorandum for consideration and discussion.

A sessional meeting of the Royal Sanitary Institute will be held at Bristol University on Saturday, March 13, at 10 a.m., when papers on "Recent Developments in the Control of Domestic Pests," "The Value of Lethane (384 Special) in the Control of Pediculosis," and "Some Problems in Nursery Provision," by Dr. H. G. H. Kearns, Dr. R. J. Irving-Bell, and Dr. Marguerite G. Hughes and Mr. H. W. Brand, respectively, will be read and discussed.

A meeting of the Pharmaceutical Society of Great Britain will be held at 17, Bloomsbury Square, W.C., on Thursday, March 11, at 7 p.m., when short papers on "Formaldehyde-gelatin in the Production of Enteric Pills and Capsules," "The Use of Stock Suspensions in Dispensing," "Ergot, the Qualitative Chemical Tests," and "The Acridine Antiseptic" will be read and discussed.

The next quarterly meeting of the Royal Medico-Psychological Association will be held at 11, Chandos Street, W., on Wednesday, March 10, at 10.30 a.m., when opening papers on "The Clinical Aspects of Prefrontal Leucotomy" by Brigadier J. R. Rees; Drs. R. Strōm-Olsen, S. L. Last, M. B. Brody, and Mr. Geoffrey C. Knight; and Dr. E. Cunningham Dax will be read. At the afternoon session, beginning at 2.15 p.m., the subject for discussion is "The Range and Technique of Prefrontal Leucotomy," and opening papers will be read by Prof. F. L. Golla, Mr. Wylie McKissock, and Mr. F. W. Willway.

The Labour Research Department (6, High Holborn, W.C.) has arranged an information and discussion conference on "Canteens, Catering, and Food Supplies," to be held at the Conway Hall, Red Lion Square, W.C., to-day (Saturday, March 6), at 2.30 p.m.

Universities and Colleges

UNIVERSITY OF LONDON

At a meeting of the Senate, held on Feb. 24, it was resolved that for the duration of the war an additional M.B., B.S. examination should be held early in February each year. The effect of this will be that the examination will be held three times in each academic year.

The William Julius Mickle Fellowship has been awarded to Prof. E. C Dodds, M.D., D.Sc., F.R.S., F R.C.P., Courtauld Professor of Biochemistry at Middlesex Hospital Medical School.

ROYAL FACULTY OF PHYSICIANS AND SURGEONS OF GLASGOW

Prof. Dugald Baird will deliver a lecture, under the auspices of the Dr. John Burns Fund, on "The Problem of the High Stillbirth and Neonatal Mortality in Scotland" in the hall of the Faculty (242, St. Vincent Street, Glasgow) on Wednesday, March 10, at 4 p m.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* the only changes of note in the number of notifications of infectious diseases during the week were decreases in the incidence of whooping-cough 99, and of scarlet fever 46; and increases in measles 1,945, and cerebrospinal fever 14.

The downward trend of scarlet fever and whooping-cough was confined to the north: there were 52 fewer cases of scarlet fever in Yorks West Riding, and 47 fewer of whooping-cough in Durham and 39 in Lancashire. In the south-eastern counties the notifications of scarlet fever rose by 59; in London the total was unchanged.

Dysentery notifications were down by 4. London and Lancashire, each with 13 cases, accounted for almost one-third of the total; the remaining 59 cases were widely distributed in twenty-three counties.

A seasonal rise of cerebrospinal fever (to 124) brings it to a higher level than during the past twenty weeks. Since the rise to epidemic proportion in the beginning of 1940 the successive peaks and the endemic levels have been progressively smaller. The cases during the past four weeks were approximately two-thirds of the total for the corresponding weeks of last year.

In *Scotland* the incidence of infectious diseases fell. Very small rises were recorded for cerebrospinal fever 2, and pneumonia 3; the trend of these diseases has been upward during the present year. The fewer cases of measles resulted from a drop in the north and the east, while in the south-eastern and western counties there was a small rise. The cities of Aberdeen and Dundee had 33 and 30 fewer cases, but rises were reported from Glasgow and Edinburgh of 9 and 18 respectively.

In *Eire* notifications of diphtheria fell from 126 to 93, and those for whooping-cough rose from 51 to 75—the latter mainly due to the outbreak in the urban and rural district of Kilrush, Co. Clare, (20 cases).

Measles

In England and Wales the number of notifications of measles rose by 1,945 during the week, and the total represents an increase of 32% on that of four weeks ago. During the week reviewed the largest increases were those of Yorks North Riding 352, Middlesex 200, London 192, Durham 192, Derbyshire 174, Kent 158, Gloucestershire 155, Buckinghamshire 140, Essex 117, Hertfordshire 108. In contrast to the general rise a considerable fall was recorded in Yorks West Riding 214, Leicestershire 128, Lincolnshire 96, Bedfordshire 94. Some of the large towns are experiencing a rather severe epidemic, and among these are Middlesbrough, Bristol, and Sheffield, where 574, 472, and 436 cases were reported during the week. In London the numbers of cases in the past four weeks were 750, 821, 933, and 1,125; the rising trend is causing some concern to the London County Council, who have issued an appeal for recruits to the nursing staff of their fever hospitals. They require 800 to 900 additional nurses. Two factors that have important influence on the situation are (*a*) the greater proportion of cases sent to hospital because the mothers are working, and (*b*) the return of children to London.

The Week Ending February 20

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 1,922, whooping-cough 1,581, diphtheria 828, measles 18,215, acute pneumonia 1,399, cerebrospinal fever 96, dysentery 89, paratyphoid 7, typhoid 6. There were 102 deaths from influenza in the great towns.

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Feb. 13.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county) (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for. (a) The 126 great towns in England and Wales (including London). (b) London (administrative county) (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

ANY QUESTIONS?

Prophylactic Use of Vitamin K

Q.—*In view of the importance of preventing haemorrhage in the newborn, is it worth while giving some form of naphthaquinone to mothers just prior to childbirth in order to prevent hypoprothrombinaemia?*

A.—The incidence of haemorrhage of the newly born is significantly reduced when vitamin K (menaphthone *B.P.* 2–5 mg.) is given to the mother not less than 5 hours before delivery. Although the subject is still controversial, and some authors doubt whether the gain is great enough to justify the cost, it would be reasonable to administer vitamin K intramuscularly to mothers as a routine, to reduce the risk of intracranial haemorrhage, and then to treat the baby with vitamin K, 1 mg. by mouth, on the first five days of life.

Prostigmin for Deafness

Q.—*Is prostigmin of use in the treatment of catarrhal deafness?*

A.—It seems that prostigmin temporarily increases the acuity of hearing, and having noticed this T. C. Davis and J. C. Rommel (*Arch. Otolaryngol.*, 1939, **29**, 751) tried it as a treatment for chronic deafness. The benefit they claimed has not been confirmed by other observers, though sometimes there is an apparent improvement which may be due to other simultaneous treatment. Houser, Campbell, and Schluederberg gave it a good trial with audiometric tests and dismiss the results as negligible.

Temperature-taking in Tuberculosis

Q.—*How long should the ordinary half-minute thermometer be left in the mouth in cases of pulmonary tuberculosis? I frequently observe readings as follows: at 2 minutes 97.5° F.; 5 minutes 98° F.; 10 minutes 98.8° F. What valuation should be placed on such readings?*

A.—Temperature-taking by ordinary clinical methods gives a relative rather than an actual observation. In the treatment of pulmonary tuberculosis changes in the type of chart are more important than the figure of any actual reading. Therefore to get a reliable chart for guidance (1) the same thermometer should always be used; (2) it should be kept in the mouth for the same time (for a half-minute thermometer it is immaterial whether the time chosen is 2 minutes or 5 minutes); (3) the temperature must always be taken at the same time each day and under the same conditions—preferably after one hour's rest—and no food or drink should have been taken for at least half an hour beforehand.

Treatment of Intermittent Claudication

Q.—*What treatment is recommended for intermittent claudication?*

A.—Intermittent venous occlusion, by a hydrostatic or electric pump, gives very good results in earlier cases of intermittent claudication. Intravenous plasma transfusions of 800 c.cm., at weekly intervals, for four or five times, benefit the pain, the trophic lesions, and the walking power.

INCOME TAX

Absence at Night: Cost of Meals, etc.

H. D. has been performing duties at a hospital clinic owing to the absence of the M.O. there. He has had to be away from his house one night a week with consequent expense for meals, etc. Is this expense deductible?

*** It depends on whether H. D.'s earnings are assessable under Schedule D or Schedule E. If, as would seem to be the case, he is in practice and has taken on this extra work as an addition to his normal work, we think the fees received may be regarded as part of the professional earnings assessable under Schedule D, and in that case the *extra* expense he is put to can be deducted for income-tax purposes. If, on the other hand, H. D. held an appointment and in effect has accepted an additional appointment, then the income from each is legally assessable separately, and the expenses in question are not strictly deductible. It might perhaps be worth while, however, even in the latter case, representing to the inspector of taxes the hardship of the case, and asking him to regard the earnings as resulting from one combined appointment, the duties being exercised in two places, and consequently necessary and allowable expenses being incurred.

Assistant Providing Car—Allowance

E. H. is employed as an assistant to a firm of doctors, and as a condition of service must supply a car. All running expenses are borne by the firm. What allowance can he claim? The car is used for professional purposes only.

*** He can claim the depreciation allowance—i.e., 20% of the cost price for the first year, and thereafter 20% of the value as written down by the percentage. The allowance as so calculated is then increased by one-fifth.

Service in the Forces—Expenses

"SURG. LIEUT." incurs expenses (*a*) as a member of professional associations, (*b*) for professional literature, and (*c*) for books and instruments. Is he entitled to any deduction or allowance on this account?

*** The question is governed by the statutory rule relating to Schedule E which provides for the deduction of expenses incurred "wholly, exclusively, and necessarily in the performance of the duties of the office." If membership of a specified association is a condition of appointment to an office, then the annual fees payable to that association are allowable; otherwise the deduction is barred by the word "necessarily." Similarly with regard to literature, instruments, etc. If an employee is required to provide them himself then the annual cost of maintenance is allowable, and not otherwise. This application of the statutory rule was supported in 1925 by the High Court in the case of Simpson *v.* Tate.

Return to Civilian Employment

"A1" joined the Forces on Jan. 7, 1941; prior to that he held an appointment at £525 per annum. He returned to civilian employment, on a salary of £600, on Jan. 15, 1943. On what basis should he be assessed?

*** Legally there is a definite break between civil and military appointments, and a change from one to another involves "cessation" of one employment and "commencement" of another, with the result that "A1" would become liable on the basis of his earnings of the current year for 1942–3 and 1943–4. If, however, he was assessed for the first year of his military service on the basis that his employment had been continuous and that basis operated adversely, the income-tax authorities will no doubt continue to regard the employment as continuous, notwithstanding his return to civilian employment, if that should now be favourable to him. ("A1" does not give sufficient details to show whether that is the case.)

LETTERS, NOTES, ETC.

"B.M.J." Lost through Enemy Action

Mr. CYRIL C. BARNARD (Librarian, London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), Mr LESLIE T. MORTON (Librarian, St. Thomas's Hospital Medical School, London, S.E.1), and Mr. W. R. LE FANU (Librarian, Royal College of Surgeons, Lincoln's Inn Fields, London, W.C.2) write: The Medical Library Association of America has given British medical libraries much help in the replacing of journals lost in transit from the U.S.A. The serious inconvenience caused by these losses in this country has been much mitigated by such help, which has been given to member and non-member libraries alike. A recent letter from the association reports the loss by enemy action of all copies of the *British Medical Journal* for March 15, 1941, and appeals for help in replacement. The above British members of the Medical Library Association would therefore be grateful if any of your readers who can spare their copies of this issue would send them to one of the addresses given. We have undertaken to forward them to medical libraries in America. So much has been done for British libraries that we welcome this opportunity to return in some measure the timely help which colleagues in America have given us.

Correction

The date on which the B.M.A. deputation met the Minister of Food to urge pasteurization of milk (*Journal*, Feb. 27, p. 265) was Feb. 18.

LONDON SATURDAY MARCH 13 1943

EPIDEMIC NAUSEA AND VOMITING

BY

W. H. BRADLEY, D.M.

A Medical Officer to the Ministry of Health

In July and December, 1935, two episodes in a widespread outbreak of nausea and vomiting in Denmark were observed by Rischel (1935) and Henningsen (1936). In March of the following year Miller and Raven (1936) recognized the same condition in a boarding-school for girls in Thanet; and in October, 1938, an outbreak occurred both in a girls' school and amongst the general population of Hayling Island (Gray, 1939). From conversations with colleagues, particularly medical officers to the public schools, it is probable that outbreaks of a similar nature had occurred in England before 1935. During recent months this comparatively trivial disorder has become much more common.*

Although the disease is of minor significance clinically and economically, it may give rise to considerable administrative uncertainty. Those who are unfamiliar with the clinical and epidemiological picture may be led to suspect food-poisoning or dysentery and be stampeded into ineffectual and wasteful action. It is important that at the present time "epidemic nausea" should be considered in the differential diagnosis of all outbreaks of gastro-enteritis, and the following incomplete account of an outbreak at present under investigation may serve to emphasize some of the differentiating points.

On Oct. 27, 1942, the medical officer of health for an urban district with a population of about 10,000 was informed by the medical officer to a girls' public boarding and day school that a number of children had been attacked almost simultaneously with vomiting and diarrhoea. Both boarding and day girls were involved. The boarders constituted three separate feeding groups, and the only aliments obviously common to all the affected children were school milk and the mains water supplied to the whole town. Since inquiry of the practitioners in the town brought to light no evidence of an explosive outbreak of dramatic proportions in the rest of the town strong suspicion fell on the school milk, originating in two accredited farms producing together about 100 gallons a day. Half of this milk was bottled and distributed to certain schools unpasteurized in 1/3-pint bottles by one of the three retail dairies in the town; the remainder was sold in larger bottles or in cans to private householders. Investigation was concentrated in this direction, the school milk being withdrawn and the retailer requested to provide the Health Department with a list of his customers in order that they might be circulated and advised to boil their milk. The retailer refused this request.

On Oct. 28 it was learnt that 120 of 400 girls in the school had been ill, but that other schools consuming the milk were not involved. Milk examined on this day was free from pathogenic organisms. However, on the 29th an explosive outbreak occurred in the boys' public boarding and day school in the town, and the Ministry of Health was asked to advise as to further action. The following account records observations made on Oct. 30 and Nov. 3.

Incidence and Age

It is unusual for patients affected with this disorder to call their doctors, since most of them begin to feel better within a few hours. The disease is not notifiable, and without a house-to-house survey no estimate of incidence among the general population can be made. Reliable information concerning attack rates was, however, obtained from a few selected samples, that concerning the girls' school being most complete. The school buildings in this instance are at present occupied by the public school proper and by an evacuated school party, the school proper occupying them in the morning and the evacuated party during the afternoon. The school proper maintains three boarding-houses, but the majority of pupils live in their homes. The evacuated party is billeted with private householders near the school, except for one small group occupying a hostel. There are thus four residential communities, each representing a separate feeding group but occupying the same building for school purposes. There is little physical contact between the school proper and the evacuated party except at midday, when members of both schools may meet in cloakrooms and corridors. The schools are independently staffed. The known attack rates during the first week of the outbreak are tabulated below:

Table showing Attack Rates during First Week of Outbreak

	Boarders			Day Girls			Total		
	Roll	Incidence	Attack Rate %	Roll	Incidence	Attack Rate %	Roll	Incidence	Attack Rate %
Girls' public school ..	85	58	68	324	123	38	409	181	44
Evacuated school ..	21	8	38	181	27	15	202	35	17

The attack rate for the general population is unlikely to have exceeded that among the day girls in the evacuated school, say 15%, although in a few households all the members were affected.

While the incidence would at first sight appear to be highest in communities of young people, in one household the ages of the persons attacked were 50, 54, 56, and 81 years, and the attack rate among the adult staff of the girls' public school was high.

Clinical Picture

Vomiting.—This was the most characteristic sign, and in young people it tended to be projectile and of great urgency. The first vomit usually contained food, but second and third vomits were of copious clear fluid only faintly bile-stained. A child who sat down to lunch feeling well "suddenly turned green" and had vomited before she could leave the room. A boy vomited on to his plate during a meal. This precipitate emesis was particularly distressing when it occurred during the night: sleeping children woke suddenly and vomited before they could get out of bed. On the other hand, projectile vomiting was by no means invariable, and a large proportion of the cases, particularly adults, did not vomit, or vomited only after a prolonged period of nausea.

Nausea.—Usually nausea was present with the vomiting, but more characteristically preceded it for a period of hours or even days, and in several cases persisted unaccompanied by emesis. Nausea, which some patients described as being indistinguishable from the sensation of sea-sickness, was associated with the feeling of fullness or of "a lump" in the epigastric angle. In a case in which it had persisted for a week the epigastrium became tender to touch.

---

* Received for publication Dec. 8, 1942.

Vertigo.—Nausea often included a sense of instability and dizziness. A desire to fall over or faint was present in some cases and patients disliked sitting up for this reason, but in few instances only did dizziness amount to true vertigo.

Aches.—Some degree of frontal headache was almost invariably present, and in some cases lasted for three to four days. Occipital headache also occurred. Headache was not persistent, but tended to come and go in spasms. Abdominal aching occurred mainly in the epigastric angle, but sometimes involved the umbilical region; in patients with diarrhoea it sometimes occurred below the umbilicus. *Pain* from colic was conspicuously absent.

Diarrhoea.—This symptom was of minor importance, and in those cases in which it occurred the stools were watery and the bowel actions hurried but not greatly increased in frequency. Mucus was not present, and in most cases the stools were normal in appearance. In one case red blood was passed, but the stool was not characteristic of dysentery.

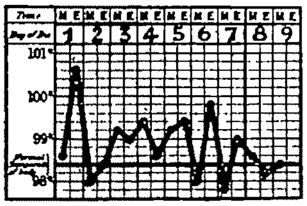
Frequency of Symptoms.—The relative frequency of the symptoms in one girls' boarding-house was as follows:

Population at risk		35
Vomiting without diarrhoea ..	11	
Vomiting with diarrhoea	7	
Diarrhoea only	1	
Nausea only	7	
Total cases	26	

Physical Signs

Central Nervous System.—When a group of these cases were seen together the impression that the central nervous system was primarily involved was a strong one, particularly when signs of gastritis or enteritis were absent. There was no evidence of dehydration, severe intoxication, or collapse. Routine examination of the central nervous system failed to detect any recognized signs apart from a suspicion of mydriasis with sluggish ocular reflexes. Widely dilated pupils were observed in some children on the first and second days of the disorder. Although the school children remained limp and tired for a few days they returned to classwork when nausea and vomiting had ceased, and their teachers did not notice any lack of co-ordination, precision, or concentration following the attack.

Temperature and Pulse.—The temperature rhythm was disturbed in almost every case in which observations were made, but rises in temperature above 100° were not numerous, although a very few cases showed rises to 102°. Pyrexia was rarely of more than 24 hours' duration. The pulse was disturbed in minor degree only. Bradycardia, which had been observed by Gray, was not characteristic in the present series. The temperature chart of one of the more persistent cases is here reproduced.



Temperature chart of one of the more persistent cases.

Alimentary System.—The appearances in the mouth were uniform and almost constant throughout the first two days. The tongue was moist and lightly covered with a white fur through which projected hyperaemic papillae. These appearances were no less striking, and could easily be confused with those seen in the first day or two of streptococcal throat infections, but the papillae were scattered evenly over the tongue surface and not confined to the tongue margins. The fauces and posterior pharyngeal wall were moderately injected in some cases, but there was no exudate on the tonsils. So suggestive were the tongue and throat appearances that swabs were taken from eight cases of nausea. One of these cultures yielded *Str. pyogenes*, Lancefield group C; the remainder gave a normal throat flora only. *Epistaxis* occurred in two children.

Examination of the abdomen did not suggest any dilatation of the stomach or increased peristalsis, and in most cases the abdominal wall moved freely and the patient was not disturbed by palpation. Sometimes the sensation of nausea was increased by epigastric pressure, but tenderness was not elicited except in three cases in which umbilical aching radiated into the right iliac fossa and tenderness over the appendix gave rise to a suspicion of appendicular involvement. These three patients made dramatic recoveries without operation.

A number of cases relapsed after an interval of about one week. Relapses were also reported by Rischel (1935) and Gray (1939).

Epidemiology

Family Outbreaks

By asking a few individual patients whether their friends or acquaintances had suffered from a similar condition a number of family outbreaks were brought to light. Chronologically the earliest involvement detected preceded the present events by five weeks, and in this instance four of six members of a household became characteristically ill almost simultaneously and had attributed their discomfort to the mutton consumed one to two and a half hours previously. In another household all of six persons were involved. First the cook and the master became ill. Two days later, on Oct. 8, 1942, while at an evening choral practice, M., a schoolgirl evacuee, was attacked with "vertigo" and giddiness, and thought she was going to faint. She left the class, and half an hour later vomited. She then slept normally for a few hours before awaking suddenly and vomiting precipitately, and about six hours later she passed one watery stool. During the next two days this evacuee's hostess and her daughter became ill, and on Oct. 10 the last of the six—another evacuee, J.—fell sick, complained of giddiness, and thought she would faint, but had neither vomiting nor diarrhoea. The two evacuees mentioned were members of the sixth form of the evacuated school party, which remained well until three weeks afterwards and which will be discussed later.

H., an elementary-school teacher aged 50, lived with her father aged 81, her sister aged 51, and a guest aged 56. On Oct. 20, 1942, the guest and the sister were ill with nausea and vomiting. On Oct. 27 the teacher felt cold and chilly, and complained of her head "swimming" and felt seasick. Next day she was "very ill" in the afternoon. "Vertigo" continued for three or four days, and a week after the onset she still had nausea and epigastric discomfort and tenderness, and wished she could be sick, but neither vomiting nor diarrhoea occurred. On the 28th her sister suddenly relapsed and vomited violently for two hours, but had negligible nausea and no diarrhoea. On the evening of the 29th her father vomited precipitately and complained of "vertigo." Nausea persisted throughout the next day, but there was no diarrhoea. H. continued to teach her class in the elementary school, but no cases had appeared amongst her pupils within seven days of the cessation of her symptoms.

H.'s nearest neighbour, who lived in an isolated house with her husband and two daughters, was breaking her fast with a cup of tea at 7 a.m. on Oct. 28, 1942, when she was seized with intense nausea and passed an urgent stool. During the morning nausea became almost intolerable and she passed more urgent stools, but it was seven hours before she vomited. Giddiness persisted throughout the 29th, and she was still feeling weak on Nov. 2. Up to this date the condition had not been transmitted to the three other members of her household. This woman had neither left her cottage nor received visitors since Oct. 24.

Community Outbreaks

The family histories described served to show that the disease was present in the town before cases appeared in the schools and that there was considerable variation in the pattern of the outbreaks in households. Similar variations were found in community outbreaks.

Girls' Public School

Junior Boarding-house (Girls).—Population at risk, 20; children known to have been attacked, 12. On Oct. 25, 1942, one child reported diarrhoea. At 5 p.m. on the 27th two young girls vomited and had passed hurried stools before bedtime. Between 5 and 8 p.m. five other girls vomited, but had no diarrhoea; and between 8 p.m. and midnight five more children vomited before they could get out of their beds. Next morning another child developed diarrhoea without vomiting. No further cases were detected during the following week.

Senior Boarding-house (Girls).—Population at risk, 35; children known to have been attacked, 26. A child was sent to bed with diarrhoea and a slight temperature on Oct. 6, 1942. On the 12th another child had precipitate vomiting during the night, and some nausea and headache persisted through next day. Fifteen days later, between 8.30 and 9 p.m. on Oct. 27, some of the younger girls began to vomit, and by midnight 11 of the 35 children had vomited and 5 others were complaining of nausea. Further cases appeared particularly amongst the older girls on the morning of Oct. 28.

Another Boarding-house (Girls).—Population at risk, 30; children known to have been attacked, 19. There is no record of alimentary upset in this series since the beginning of term until Oct. 27, when between 8 p.m. of that day and 8.30 a.m. of the 28th 14 girls vomited. Cases continued to occur throughout the latter day, and by the 29th 17 children had vomited and 2 had had nausea only. Two of the staff became ill 24 hours after the first appearance of the disease in the children.

Evacuated Day School Hostel.—Population at risk, 21; children known to have been attacked, 8. The ages of these girls range from 7 to 15 years, but the outbreak was confined to 8 of the 10 juniors, the seniors and staff escaping. The first case occurred at 1.40 p.m. on Oct. 27, 1942, when a child vomited precipitately at lunchtime before she had eaten any of the meal. She improved during the next day, but vomited again on the following night, and subsequently passed blood in her stool for three days. The second case in this hostel appeared at 7.30 p.m. on Oct. 27. At 8.45 p.m., soon after the children had gone to bed, others were taken ill, and between 2.30 a.m. and 5 a.m. of the 28th three further cases vomited. None of these children developed diarrhoea.

Evacuated Day School; Billeted Children.—Population at risk, 181; children attacked, 27. Although only 27 of these children were absent from school with this condition it is probable that some nauseated children continued to attend classes. Furthermore, new cases were still appearing on Nov. 3, when these notes were made, and the final score is unknown. Some billeted children in the junior classes were attacked at the same time as their fellow pupils living in the hostel—that is, on Oct. 27 and 28. The timing of the attack on sixth-form girls was entirely different. All these girls lived in billets or with their families. The cases M. and J., mentioned under family outbreaks, were ill on Oct. 8 and 10 respectively. Of the remaining 18 girls in this form nine became ill, three without vomiting—on Oct. 28 (one case), Oct. 30 (two cases), Oct. 31 (one case), Nov. 2 (one case), Nov. 3 (two cases), Nov. 4 (one case), Nov. 11 (one case) respectively—and nine had remained well.

Boys' Public School

The majority of pupils attending this school are day boys, many of whom have sisters in the girls' public school. The two public schools draw their day pupils from rather exclusive social and economic levels, representing virtually the same home environments. It is known that day boys were already affected on Oct. 26, and the attack rate appeared to be of the same magnitude as among the day girls. The three boarding-houses suffered more explosive outbreaks, two of which are summarized below.

"O" House.—Population at risk, 36 junior boys; number known to have been attacked, 15. The house master, his wife, his daughter, his staff, and the 36 boys constitute one feeding group. The 8-year-old daughter attends the girls' public school and is a class-mate with girls in the junior boarding-house there. At 5.30 p.m. on Oct. 27, after returning from the girls' school to "O" House, she vomited, and continued to do so throughout the night. She had no diarrhoea. Forty-eight hours later her mother became nauseated and, after five hours' increasing discomfort, vomited at 10 p.m. on the 29th. The same evening 10 of the boys were attacked, most of them between 4 and 7 p.m., and the matron also developed nausea, which persisted for four days before she vomited. At first sight this sequence suggests that the house master's daughter was the primary case in this community. Further inquiry brought to light a boy in the house with diarrhoea starting on Oct. 23, one with nausea on the 25th, and two further cases of vomiting on the 28th. It is therefore not improbable that, if the spread of this disease depends on contact, there were at least two primary sources of infection in this house.

St. J. House.—Population at risk, 42; number attacked, 22. This house constitutes a separate feeding group and occupies a neighbouring building, 100 yards away from "O" House. The recorded incidence of nausea and vomiting was as follows: Oct. 28, 10 cases; Oct. 29, 8; Oct. 30, 2; Oct. 31, 0; Nov. 1, 1; Nov. 5, 1. The majority of the 10 boys attacked on Oct. 28 were unable to get up on that morning. The peak of the wave in this series was therefore at least 33 hours before the peak in "O" House.

Bacteriology.—Three specimens of milk from the suspected source and twelve specimens of vomit and faeces were examined at an Emergency Public Health Laboratory, all with negative findings.

Discussion

It is difficult to avoid the impression that the explosive outbreak reported to the medical officer of health was in fact the summit of a wave of disease which had been mounting not only in the town but also in some of the communities for some days. This impression is strengthened by the observation that the peaks of the several parts of what at first sight appear to be one explosion do not coincide but range over a period of days. This pattern is unlikely to be produced by poisoning from food simultaneously consumed, but food-poisoning cannot be dismissed on these grounds alone. Each of the several groups of cases discussed was independently fed on food obtained from different sources and prepared separately, and the pattern may have arisen if a common aliment had been used on one day in one house and on another day in another house. Investigation of this possibility was conducted on the assumption that if the symptoms were due to ingestion of a toxic factor in food the incubation period was in all probability a matter of a few hours rather than days. A peculiarity of the outbreak was that one could not identify any single meal as having been consumed at a reasonably constant interval before the onset of symptoms in the several groups: considering only those cases occurring on the day of maximum incidence, the last common meal was breakfast in one house, dinner in another, tea in another, and supper in a fourth. These variations do not necessarily argue against the disorder being *ex alimentatione*; they merely suggest that if the cause of the trouble was ingestion of a common aliment the incubation period was variable, usually exceeded 12 hours, and may have been of several days' duration. Other considerations suggest that if the toxic factor was food-borne it withstood cooking.

In the absence of more exact knowledge as to the nature of the toxic factor or of the incubation period, and without minutely detailed food lists and menus covering several days, such widely distributed non-perishable items as dried eggs or dried milk, chocolate, etc., could not be excluded. Liquid milk could, however, be excluded with some degree of certainty on the grounds that (1) some of the patients becoming ill during the peaks of the wave did not take milk from any source and others did not take school milk, which was the only source suspected; (2) the same milk, bottled and delivered at the same time and under identical conditions and consumed at approximately the same time, did not give rise to disease in some of the schools supplied; (3) only by the remotest chance could contaminated milk have been distributed so as to give rise to the disease in one group on one day and in other groups on other days. Furthermore, the milk was withdrawn on the morning of Oct. 28, but this withdrawal did not prevent the appearance of explosions in some communities subsequent to this date. It is interesting to note that the girls' school milk was all delivered at the school at the same time, but was consumed at different times of the day by the different groups of children affected (junior girls' public school, 10.30 a.m.; senior girls' public school, 11.45 a.m.; evacuated girls' school, 4.30 p.m.), and there is no constant relation between these times and the times of onset of illness in the several groups. All school milk was consumed on the day of delivery.

Conclusion

Previous writers have concluded that epidemic nausea and vomiting is an upper respiratory infection with an incubation period of from two to seven days, probably due to an unknown virus. The present outbreak strengthened the impression that the disease is communicable and that the portal of entry is the upper respiratory passages. The incubation period was probably within the range of from two to seven days, but could not be determined accurately. Infection *ex alimentatione* immediately preceding the attack was excluded with some confidence by the circumstances. An alimentary vehicle consumed a few days before the appearance of symptoms could not be excluded, but as a cause was thought to be improbable.

TWO CASES OF RUBELLA MENINGO-ENCEPHALITIS

BY

R. I. C. BRADFORD, M.B., B.Ch.

Surg. Lieut., R.N.V.R.

The occurrence of meningo-encephalitis in association with rubella is exceedingly rare. Taylor (1937), in his account of meningo-encephalitis following German measles, states that only 12 other cases had been reported up to that date.

Case I

A Naval Air Arm observer aged 19 was admitted to the zymotic ward on June 2, 1942, with the diagnosis of meningitis. His communication sheet stated that on May 29 he reported to the sick bay at his own depot with a typical rubelliform rash, cervical adenitis, and slight general malaise. There had been an epidemic of rubella in this establishment immediately prior to this date. He was diagnosed and treated accordingly. On June 1 he complained of severe frontal headache. His temperature was normal. The duty medical officer noticed that the right pupil was larger than the left. No other abnormal signs were reported. Next day the headache was worse; temperature 100°; pulse 80; tongue heavily furred; severe pain on flexion of neck, and weakly positive Kernig's sign present both sides; pupils equal and reacting sluggishly to light.

June 2.—On admission he lay curled up in bed, face towards the wall and away from the light. He was mildly annoyed at being disturbed for examination, and somewhat drowsy, but withal intelligent and co-operative. Some exposure phobia was evident, as is commonly found in meningitic cases. He was obviously feeling ill: face pale, tongue furred, and remains of what might have been a rubelliform rash over his trunk, most pronounced on the back. Temperature 100.8°. Glands in posterior angle of neck enlarged and tender. No Koplik's spots seen on buccal mucous membrane. Pupils equal in size; reactions brisk. All reflexes normal. Babinski's sign absent. Kernig's sign negative. Marked nuchal rigidity with pain on flexion. Heart, lungs, and abdomen normal. Lumbar puncture was performed and 16 c.cm. of clear fluid withdrawn under increased pressure (Table I). Sulphapyridine was administered as a routine measure in view of the possibility of meningococcal meningitis, several cases of which had recently been in the ward.

June 3.—Condition much the same. Temperature 100°. Kernig's sign positive; marked neck rigidity. Knee-jerks rather brisk. Doubtful plantar response.

June 5.—Neck rigidity less severe. Flexor plantar response. Knee-jerks normal. Kernig's sign negative. Pyrexial still. Lumbar puncture repeated: 20 c.cm. of clear yellow fluid withdrawn under increased pressure.

June 6.—Temperature 99°. Condition improved. Complained of slight cough. A few crepitations heard at left base.

June 8.—Temperature rising. No clinical change.

June 12.—A general marked rubelliform rash again present over trunk and proximal part of limbs, pink and papular in nature, typical of rubella. A few spots also present on face. No Koplik's spots seen. Tender cervical adenitis present. Temperature 100°. C.N.S. normal. Lumbar puncture performed: 15 c.cm. of clear fluid obtained, not under pressure.

June 14.—Rash completely gone. No skin staining left. No symptoms beyond slight headache. C.N.S. normal.

The patient made an uneventful recovery from this date and went through his period of convalescence without the appearance of sequelae.

TABLE I.—*Results of C.S.F. Examination in Case I*

Date	Protein (mg./100 c.cm.)	Cells per c.mm.	Lymphocytes	Polymorphs	Sugar (mg./100 c.cm.)	Chlorides (mg./100 c.cm.)	Organisms	Red blood cells	Fibrin	Lange Gold Curve

5/6/42	100 Glob. +	20	94%	6%	60	720	Nil	+	+	3444553100
10/6/42	50	50	96%	4%	30 3	730	Nil	—	—	0012332210

Wassermann reaction negative

In view of the typical nature of the rash in this case, together with the fact of the rubella epidemic in progress, the diagnosis of rubella must be considered as confirmed. The occurrence of a second rubelliform rash is difficult to explain unless it be considered as a relapse, which, although rare in rubella, is not unknown. The C.S.F. findings are interesting in view of the marked increase of protein, especially with regard to its dissociation from the cell count. A similar dissociation is found in cerebral arteriosclerosis, some cranial tumours, and spinal tumours. This point in common with arteriosclerosis is worthy of comment in so far as Taylor (1937), describing a case of encephalomyelitis which came to the post-mortem table, mentions the extreme degree of arterial degenerative proliferation found in the brain together with perivascular cuffing of small lymphocytes with occasional large ones. The red blood cells and the minute fibrin clot found in the second specimen of C.S.F. were probably an artefact due to the previous lumbar puncture.

Another case of rubella which portrayed the signs and symptoms of encephalitis is included in the records of this hospital for the year 1940.

Case II

Feb. 5, 1940.—During a large epidemic of rubella a rating aged 18 was admitted with the typical rash, cervical adenitis, and sore throat. No Koplik's spots were seen, and there were few signs of respiratory catarrh or conjunctivitis. We had 200 cases of rubella in the hospital at this time.

Feb. 10.—The patient, who had been progressing normally apart from a mild degree of pharyngitis, vomited a greenish fluid several times and had a small epistaxis. He complained of headache. Temperature rose to 101.2°. He was tender in the right hypochondrium and was thought to have gastritis. A slight cough was present.

Feb. 12.—Patient vomited again. He was found to be extremely listless, drowsy, and emotionally unstable. Was easily tired and unable to concentrate on any one thing except for a very short time. Articulation was poor, with a tendency to mumble. No physical abnormality was detected. Blood urea 36.5 mg., sugar 104.6 mg. per 100 c.cm.

Feb. 14.—Still vomiting. Very ataxic. Could barely stand even with feet well apart. Marked emotional instability present. Right pupil larger than left: reactions normal. Optic disks showed faint blurring of edges. Other cranial nerves intact. Investigation of the C.N.S. showed impaired muscle sense when tested by movements of feet or fingers. Finger–nose test especially bad, the finger alighting well up the forehead. Kernig's sign negative. Remainder of C.N.S. normal. No neck rigidity. The *status quo* was preserved during the next 9 days, with slight improvement.

Feb. 23.—Lumbar puncture performed (Table II). Now apyrexial, and remained so throughout rest of illness and convalescence.

Feb. 25.—Considerable vomiting, projectile in nature, without nausea and preceded by bouts of severe headache. C.N.S. completely normal.

Feb. 27.—Lumbar puncture performed and 8 c.cm. of clear fluid withdrawn, not under pressure.

From this date the patient's condition improved rapidly; the vomiting ceased, headache disappeared, and the central nervous signs remained normal. A further lumbar puncture was performed on March 12, 1940. There were no abnormal characteristics about this fluid, and, since the patient was by now completely recovered, he was sent to a convalescent home and thence on sick leave. There were no noticeable sequelae.

TABLE II.—*C.S.F. Results in Case II*

Date	Protein (mg./100 c.cm.)	Cells per c.mm.	Lymphocytes	Sugar (mg./100 c.cm.)	Chlorides (mg./100 c.cm.	Organisms	Lange Gold Curve
23/2/40	70	20	++	40	710	Nil T.B. not found	0022221000
27/2/40	40	8	++	—	—	Nil	0011000000
	Wassermann reaction negative						

The diagnosis of rubella, as in Case I, does not seem open to reasonable doubt. Meningism was not present at any stage, and the central nervous signs and symptoms were those of an encephalitis with resulting increase in cerebral pressure.

Commentary

Complications of any variety during an attack of rubella are very rare, and involvement of the central nervous system is the least common of these. The cases of this type so far reported include manifestations of meningitis, encephalomyelitis, polyneuritis, and ascending paralysis of the Landry variety. At least two of these cases were fatal.

The necropsy on the 18-year-old girl described by Taylor (1937) revealed the typical picture of an acute to subacute encephalomyelitis with demyelination most pronounced in the perivascular regions, as may be found in encephalitis associated with the exanthemata, such as measles, small-pox, and mumps. According to Russell Brain (1940) the cause of this type of encephalitis is still unknown. The former view that it is due to the virus of the exanthem in question is in disfavour owing to failure to reproduce experimentally the pathological picture by means of the virus. An alternative opinion, that the condition is brought about by another virus common to all patients and normally latent but activated by the exanthem, would explain the similarity of pathological features in all cases and also the fact that encephalitis of this nature may arise with apparent spontaneity unpreceded by an infection. No such virus has, however, so far been demonstrated. Finley (1937) suggests that the encephalitis may be an allergic reaction in the brain following the general eruption. This is in accordance with the finding of Rivers and Schwentker (1935) that a demyelinating encephalomyelitis could be produced in monkeys by repeated injection of brain material.

I am grateful to Surg. Cmdr. Mussen, R.N., for bringing Case II to my notice, and for his advice in the compilation of this account; also to Surg. Rear-Admiral Bradbury, R.N., and Surg. Capt. Parker, R.N., for permission to publish it.

In a discussion on bacteriaemic staphylococcal infection, Champ Lyons (*Surg. Gynec. Obstet.*, 1942, 74, 41) observes that the importance of thrombophlebitis in the production of metastatic abscesses was recognized by John Hunter. He quotes Topley to the effect that in a bacteriaemic staphylococcal infection "the cocci are carried from the original focus of infection in detached fragments of an infected thrombus." Lyons presents evidence in support of this view, and believes that pulmonary thrombophlebitis as a factor in the perpetuation of a staphylococcal bacteriaemia may be likened to a left-sided endocarditis.

PLANNING FOR THE TREATMENT OF HEAD INJURIES*

BY

HUGH CAIRNS, D.M., F.R.C.S.

Brigadier, Consultant Neurosurgeon; Nuffield Professor of Surgery, Oxford

The war has given impetus to the study of head injuries, and information is now available which should assist in the formulation of plans for post-war medical services.

I. Plans should be based on a Survey of Unselected Material

Before the war, with few notable exceptions, specialists responsible for teaching on head injuries saw an undue proportion of the severe cases and those in which compensation or litigation was pending. Although as long ago as 1932 Ritchie Russell had shown that the majority of patients with head injury made a satisfactory return to work within six months, treatment and prognosis of head injuries continued for the most part to be governed by pathological doctrines which implied, or were thought to imply, that bruising of the brain was an almost invariable accompaniment of even minor concussion, and that the bruising took a long time to resolve and might continue to produce symptoms for a number of years. Patients are still encountered who have been confined to bed for weeks or months after relatively trivial head injuries, and have been warned that because of brain damage they cannot expect to resume full normal activity for periods of months or a year.

There is still considerable controversy about the pathological processes in head injury, but in the special centres established since the outbreak of war comprehensive survey of head injuries is accumulating an impressive number of facts which show that the picture of the late results of blunt head injury† has been painted blacker than it really is. Thus, in a military hospital for head injuries, in a series of 237 acute cases of head injury in the fighting Services (not including fatal cases, but otherwise unselected), Symonds and Ritchie Russell (1943) found that 80% were successfully returned to duty, the majority within three months. Among civilians Eric Guttmann (1943) obtained similar results in a consecutive series of 158 wage-earners admitted to the Radcliffe Infirmary, Oxford, suffering from head injury: 25% returned to work within three weeks, 50% in between three and nine weeks, and only 8 patients had not returned to work within six months. In Guttmann's series there had been an initial hospital mortality of 4%.

These are the results in unselected hospital material from a mixed urban and rural area, at a time of "comparatively standardized and favourable social conditions, when everybody has the choice of well-paid jobs and most employers are ready to facilitate gradual return to work." In civilian head injuries, permanently incapacitating brain damage appears to be an uncommon event—among Guttmann's 158 wage-earners there were only 2 patients so affected—and early return to work may be expected in the majority. The results suggest the need for revision of teaching on the subject of head injuries. They also suggest that where problems of compensation arise settlement should be made at an earlier date than has been customary in the past.

II. Where should Head Injury Patients be Treated?

Accident cases are usually taken to the nearest hospital, and it would be difficult to devise machinery for primary segregation of head cases in special centres. Guttmann found that 30% of his head-injury patients had major injuries in other parts of the body, such as fractures of long bones, and this fact favours the current practice of sending all accidents to the general hospital. There is little doubt, however, that, in the general hospital, accident cases should be segregated in an accident service, as has been done at Birmingham and Oxford, under the care of surgeons who particularize in accident work and who have special facilities for resuscitation.

Since the majority of head injuries are evidently mild and, when treated correctly, uncomplicated, it would be reasonable to expect that the *trained* accident surgeon should himself be able to see the majority of his head-injury cases through to the stage of return to full work, with the assistance of the general practitioner, the industrial doctor, and the social worker. The services of the nearest neurosurgeon would be sought in head injuries which were complicated by severe damage to the brain or skull and in those cases which were not recovering according to expectation. When fit to be moved such cases should be transferred to head-injury centres.

---

* Based on a paper read to a meeting of consultants of the combined Services at Reading, Nov. 28, 1942.

† Gunshot wounds of the head are not considered in this paper. They constitute a separate problem.

III. The Need for Statistics

Planning for head-injury centres (and for accident services) after the war would be assisted by more precise knowledge of the number, type, and distribution of accidents than seems to be available at present.

In Britain road accidents of all types amount to about 230,000 a year, industrial accidents (exclusive of mines and certain other industries) to about 270,000 a year, and mining accidents to about 133,000 a year (Safety in Mines Research Board, 1937). I have not found any information about the number of accidents which occur at home and at play, but in the U.S.A. in 1940 the deaths from accidents in the home almost equalled those from motor vehicles (National Safety Council, Chicago, 1941).

These figures do not discriminate between the patient requiring in-patient hospital treatment and the man who is so mildly injured that he can be treated at home and is able to return to work within a few days. In 1935, of the 1,300,000 accident cases in this country, only 136,000 were treated as in-patients (Report on Rehabilitation, 1939). The percentage of head inuries may vary from one type of accident to another. Of accident cases admitted to the Radcliffe Infirmary—mainly road accidents—30% showed head injury. On the other hand, in occupational accidents in the U.S.A., assessed from compensation data, head injuries amounted to no more than 7%. in British mines in 1935 the proportion of head injuries was also 7% (Safety in Mines Research Board, 1937).

Clearly, more exact information is wanted, particularly in regard to patients requiring in-patient hospital treatment. It is reasonably certain, however, that there are many more head injuries each year than could be treated by the neurosurgeons. Their function should be, along with neurologists and psychiatrists, to treat the cases presenting special difficulties.

IV. Rehabilitation

The accident surgeon, or someone on his staff, should have a clear understanding of the problems of treatment and rehabilitation of head-injury patients. Operation is often required for the repair of scalp wounds, but for other purposes only in a limited number of cases—according to Rowbotham (1942) in about 5%. Neglect of a meticulous surgical technique in closing the scalp may wreck the result in otherwise favourable cases, as Botterell and Jefferson (1942) have pointed out. In the cases of Symonds and Russell (1943) and Eric Güttmann (1943) the methods of treatment were simple and did not include any dehydration. The patient was allowed to get up gradually soon after he had recovered consciousness. He was examined thoroughly to see that there was no residual brain damage, and his personality was assessed by a study of his past, social, and family histories. An important part of the treatment is reassurance of the patient and his relatives. In the cases from the fighting Services, occupational therapy and graduated physical training were employed; these patients had to be rendered fit for full duty in the Army or R.A.F. In the civilian cases, on the other hand, no such measures were used: the patient was discharged to his home soon after he was able to get about, with instructions to report at the out-patient department on a date a little before the time at which it was estimated he might be fit for work again. The patient was advised to take graduated exercise of his own choice, a letter was sent to his family doctor, and he was seen by appointment in the out-patient department from time to time, by those who had looked after him in the acute stage, until he was once more in his stride at work. Difficulties of a psychological or social character which had been elicited by the preliminary study of personality or at the subsequent out-patient visits were dealt with by explanation and reassurance, and by visits of the social worker (who attended all out-patient sessions) to the home or to the man's employers.

Guttmann's work suggests that in the majority of head injuries in civilians the main factors in rehabilitation are the doctor's knowledge of the patient and of his social conditions, as well as of his injury, and a sustained interest in him until he is once more back at work. It really amounts to psychological management, but I have avoided using the word "psychological" lest it be thought that this process of rehabilitation requires as a routine the services of the psychological specialist or the use of elaborate psychological techniques. Handling of most patients along common-sense psychological lines should not be beyond the powers of the competent accident surgeon, who starts, moreover, with the initial advantage of having helped the patient through the acute stage of his illness. In limb injuries, though all the emphasis is placed on physical re-education (Report of the Interdepartmental Committee on Rehabilitation, 1943), I suspect that the psychological side is probably just as important as it is after head injuries, and that in protracted cases return to work is as often delayed by psychological factors as by the physical condition of the limb.*

If Guttmann's work is confirmed there is clearly no need for institutional rehabilitation in the majority of cases of civilian head injury. Institutional rehabilitation would be required, however, for the severe or recalcitrant cases and for those whose home conditions were unfavourable. The proportion requiring institutional treatment might be expected to vary with the social conditions at the time.

Addendum

Recent planning for rehabilitation of disabled persons raises some doubts as to whether the problem of restoring the sick and injured to full work is clearly understood by the planners. According to the Beveridge Report (Beveridge, 1942), rehabilitation is "a new field" of remedial activity. The Tomlinson Report (Report of the Interdepartmental Committee on Rehabilitation, 1943) states that "rehabilitation in its strictly medical sense means the process of preventing or restoring the loss of muscle tone, restoring the full functions of the limbs, and maintaining the patient's general health and strength. (This is apart from special rehabilitation treatment required for particular diseases such as tuberculosis.)" The report recommends the institution of a diploma "to cover the special needs of rehabilitation." Some readers might conclude from these statements that rehabilitation is a new technique of treatment on physical lines, to be conducted by specialists.

There is nothing new about rehabilitation. For example, it has been practised systematically for over 50 years by those responsible for the care of the blind and to what high standard this work has been raised in this country may be seen in the British Council's fine documentary film *Out of the Night*. In each broad group of maladies the methods of after-care are to a considerable extent specialized. In the case of blindness this is obvious. After limb injuries the doctor who is responsible for getting the patient fit for work must be competent to judge whether the position of the bone and the union of the fracture are satisfactory; and in this group of cases physical re-education is important. After head injuries rehabilitation must always be partly based on thorough neurological examination; physical re-education, as has previously been pointed out (Cairns, 1942a, 1942b), plays a small part.

If there is one thing common to rehabilitation after all varieties of accident and disease it is the need for study and understanding of the personality of the patient and of his social circumstances, and this should be the duty of every doctor who treats a patient. The "new" things in rehabilitation are the more general realization by the medical profession of its responsibilities for convalescence of all patients, and the formal recognition of the part which a patient's personality plays in his readjustment after injury or disease. The importance of the social worker in rehabilitation is also becoming more generally accepted.

---

* The importance of the psychological factor in limb injuries was clearly recognized by the Delevingne Committee, who wrote (Report of Interdepartmental Committee on Rehabilitation, 1939, p. 52): "The rate and degree of recovery will depend not only on the nature of the treatment given for the physical injury but also on the individual mental 'make-up' of the injured man"; and again, "The witnesses generally were agreed that a psychological factor was present in varying degree in the majority of cases, and that this was often a dominant factor in retarding recovery."

It would be harmful if people came to think that rehabilitation consisted of physiotherapy or some other technical method of treatment, or that it was the particular province of any group of specialists. To set up a specialty of rehabilitation would be akin to establishing specialties for diagnosis or for therapy. In a national scheme all varieties of medical specialist would be involved, and the general practitioner and the industrial doctor would be more essential than any of them. The whole medical profession would be involved. In ancillary services the social worker would be at least as important as the masseur.

Extension of rehabilitation to all sick and injured persons would obviously require a large increase of social workers and doctors, whose training for this work would tend to become standardized. But in each group of diseases or injuries successful rehabilitation depends to some extent on special knowledge of the disabilities produced by the disease or injury in question, and of the reactions of patients to these disabilities. Trained experts would deal with the cases requiring institutional after-care, mostly in special centres, from which advances in knowledge of the social aspects of ill-health might be expected. But, if the experiences with head injuries are any guide, it would seem that much of the after-care of the nation's sick and injured should continue to be directed by the doctor who treats the patient in the acute stage of his illness. If in his student days he can be taught the after-care of patients in a practical way, and if he can be supplied with more precise knowledge of the social prognosis of diseases, and with adequate assistance from social services and from employers, this task should not be beyond him.

REHABILITATION IN AN E.M.S. ORTHOPAEDIC UNIT

BY

S. ALAN S. MALKIN, M.B., B.S., F.R.C.S.Ed.

Surgeon-in-Charge, Harlow Wood Orthopaedic Hospital, Nottingham; Orthopaedic Surgeon, Mansfield and District General Hospital

AND

GILBERT PARKER, M.B., Ch.B., F.R.C.S.Ed.

Hon. Assistant Surgeon, North Riding Infirmary, Middlesbrough; Acting Assistant Surgeon, Harlow Wood Orthopaedic Hospital, Nottingham

The establishment of orthopaedic centres in the Emergency Medical Service stimulated those working in them to tackle the problem of rehabilitation, already carefully investigated by the Delevingne Committee. With few exceptions it had been the custom in civilian practice to discharge a patient when fit for light work and still maintain some supervision of his further recovery as an out-patient. In the case of Service patients (who have formed the majority of those treated in this centre) the disposal was not so easy, for discharge from hospital removed them completely from the supervision of the surgeon. The danger of too early discharge from surgical supervision is easily seen; a typical example will make the point clear. In civilian work it had been our practice to discharge meniscectomy cases from hospital two weeks after operation and to continue treatment as out-patients. Service patients retained for a further fortnight have usually acquired full knee movement, have a fair quadriceps and no effusion, and are able to walk several miles without undue pain or fatigue. No doubt some of these men, if returned to light duties, would rehabilitate themselves, but many would sustain some minor trauma, develop effusion, and be sent back to hospital some months later with a history of recurrent effusion and marked quadriceps insufficiency. The problem of rehabilitating such patients is then much more difficult than if it had been dealt with in the immediate post-operative period.

Before discharge from hospital a patient should fall into one of the following groups:

(*a*) Fit to return to full duties in his original category.

(*b*) Fit to return to duty in a reduced category; usually cases which have progressed satisfactorily, but in which some residual disability remains—e.g., limitation of elbow movement after fractures in the region of the elbow-joint.

(*c*) Fit to be transferred to a Command convalescent depot and undergo graduated Army training. This includes cases in groups (*a*) and (*b*); it also includes patients who have improved beyond the limit of possible relapse but who are not quite fit for duty—e.g., lower-limb fracture patients who can walk and run easily and require only time and graduated use to complete their full recovery.

(*d*) Patients who are unfit for Service duties and are discharged from the Service. These fall into three groups: (i) Patients fit to return to their full pre-Service occupation; (ii) patients unfit to follow their pre-Service occupations, but fit to undergo training at a Ministry of Labour training establishment; (iii) severely disabled patients who require vocational training.

The majority of the cases so far treated have been in group (*a*), (*b*), or (*c*).

Organization

When the need for a rehabilitation annexe was appreciated we were fortunate in securing for our purpose a country house, within reasonable distance of the hospital yet far enough away to make a definite break in hospitalization. The house, capable of accommodating 50 patients, is situated in ample grounds, with two large lawns suitable for outdoor games and exercises, a large indoor riding school (now converted into a gymnasium), and an open-air swimming pool. Outbuildings have been converted into recreation rooms. As the work progressed and the value of removing ambulatory cases from a hospital atmosphere became obvious, the original annexe was found to be too small, and near-by B.R.C.S. auxiliary hospitals were utilized as subsidiary rehabilitation centres.

The rehabilitation annexe is staffed by a resident masseuse and P.T. instructor. Each auxiliary hospital has an Army P.T. instructor attached. An occupational-therapy hut has been established at the parent hospital and liaison with the annexes is made through regular visits of one of the staff.

Auxiliary Hospitals

The relation between the parent hospital and the auxiliary hospitals, and the place of the latter in the scheme of rehabilitation, will best be appreciated by following the progress of patients with fractures of the tibia and fibula from the hospital, through the auxiliary hospital to the rehabilitation annexe.

Rehabilitation, it has been stated, begins not in a special centre but in a hospital bed, and ends with a return to full pre-accident activity. All bed patients perform general and special bed exercises regularly. For those confined to bed with leg injuries occupational therapy of a remedial nature is not possible, but diversional work is started in bed. We are fortunate in the situation of our hospital in pleasant country surroundings; beds are pushed out of doors in good weather, and even if the patient's stay in bed is prolonged there is no need for him to see "only the stone walls of hospital wards" (Watson-Jones, 1942).

As soon as leg-plaster cases are considered suitable for walking a sole-plate is applied to the plaster. This consists of a wooden plate with heel and metatarsal bar, the heel and bar being shod with rubber. We prefer this to the Böhler iron, as a heel-and-toe gait (so rarely attained with a Böhler iron) is easily possible with this sole-plate. Patients walk first with the aid of crutches and then with two sticks. Later they may discard their sticks; but we are in no hurry for them to do this, and prefer that they should retain the sticks and walk with a normal gait rather than that they should discard them and acquire a limp. When a patient is walking satisfactorily in plaster he is transferred to one of the associated auxiliary hospitals. To these auxiliary hospitals go all cases in walking plasters, upper-limb fractures in and out of plasters, etc.

Here the day begins with general exercises in which all patients join. Later, group exercises are carried out, particularly directed to the affected limb. We find general exercises *en masse* useful, as the men in plaster vie with those out of plaster in the energy of their movements, and it is remarkable how small a disability a long leg plaster can become. Exercises are followed by and interspersed with organized games. Those unable to take part in organized games indulge in less energetic pastimes: croquet is a particular favourite with the early walking-plaster cases, and a man who says he can walk only a few hundred yards without tiring will walk much farther in the course of an afternoon's heated croquet.

We endeavour to find jobs at the auxiliary hospitals to act as occupations with a therapeutic value, although diversional work is continued in the evenings. In addition to the ordinary fatigues of bed-making and keeping their rooms tidy, the men help in the kitchens (washing-up is a useful exercise for wrist and finger injuries) and in the gardens, mowing the lawns, weeding, and keeping the paths tidy: following a motor lawn-mower is a helpful method of re-educating slow walkers. The more capable men have helped with harvesting and flax-gathering.

At the appropriate time the patient in plaster is returned to the parent hospital for review. The plaster is removed, the limb examined, and check radiographs taken. If the fracture is not soundly united plaster is reapplied, and the man returns to the auxiliary hospital for a further period. When union is sound the patient mobilizes the limb in bed for a few days, and then walks under the supervision of a masseuse. When he is walking satisfactorily he is transferred to the rehabilitation annexe.

Rehabilitation Annexe

To this annexe are transferred all cases of fracture out of plaster (except minor cases requiring little rehabilitation), fractured spines, both in and out of plaster, severe soft-tissue injuries, and all knee-joint injuries—e.g., cartilages three weeks after operation. During the year Sept., 1941, to Aug., 1942, 295 patients were admitted to this annexe. The majority of them had sustained lower-limb injuries: there were 87 cases of lower-limb fractures and 155 cases of knee-joint injuries, including meniscectomies and fractures into the knee-joint.

Work begins at 8.30 a.m. with half an hour of general P.T., in which all the men join, and, so far as is possible with the limited staff available, the patient's day is organized from then onwards until 4.30 p.m. Following the communal exercises, the men are split into groups according to their capacity and the site of their injury. One group may have a spell of graded exercises, a second group perform resistance exercises in the gymnasium, whilst a third group indulge in remedial games. All treatment, whether in P.T. classes or by resistance exercises, etc., is liberally interspersed with rests. We must never overtire the muscles we are trying to redevelop, nor throw too much strain on a joint which is mobilizing and not yet controlled by sufficiently strong muscles. To hurt the patient by too vigorous or too prolonged treatment is not only to lose his confidence but to retard his progress. A certain amount of pain is inevitable as a joint released from plaster begins to mobilize, but by the judicious graduation of exercises, the use of radiant-heat baths, massage, novocain injections, and manipulation in selected cases, treatment can proceed with minimal discomfort.

The morning's work ends with a period of organized games or swimming before lunch. In the afternoon a similar programme is carried out, games taking up a larger proportion of the time, until tea-time. From tea-time onwards (about 4.30 p.m.) the men are free to do as they please. There are facilities for indoor games. Many walk in the surrounding country in the summer; a larger number prefer to continue the diversional work they have learnt as bed patients in the parent hospital.

Knee-joint Injuries

All cases of meniscectomy are transferred to the rehabilitation annexe three weeks after operation. The range of knee-joint movement is measured, the presence or absence of effusion noted, and the quadriceps power estimated by weight and pulley. Treatment is directed towards redeveloping the quadriceps. Regular quadriceps drill in groups under supervision is instituted, and the men are instructed to contract their muscles at all times during the day. Quadriceps drill has already been taught pre-operatively and carried out post-operatively at the parent hospital, but some patients are apt to be forgetful or lazy unless a supervised routine is introduced: in addition, by performing the drill under supervision one is able to get the last ounce out of a quadriceps contraction. A definite rhythm is introduced into the exercise, one of the more advanced patients acting as "stroke." Faradism is not used as a routine. There are some patients, however, who appear to have lost the idea of how to contract their muscles. These men receive faradic treatment, being encouraged to try to hold voluntarily the contraction obtained by electrical stimulation. When they have rediscovered the knack of producing a really good contraction themselves the faradism is discontinued.

If there is no effusion or only a minimal effusion (as in the majority of cases on arrival at the annexe) the patient joins a class doing light P.T. Exercises are mainly non-weight-bearing at first, progressing to weight-bearing exercises by the end of the first week. General exercises are also introduced. Careful supervision is maintained, any tendency to effusion being considered a contraindication to increasing the difficulty of the exercise. After the first week it is usually safe to introduce group games—e.g., basket-ball and ground hand-ball. Nicoll (1941) has drawn attention to the risk of introducing games too early in leg cases, on account of the danger of sprains when joints are not adequately controlled by muscles. In the early stages of recovery we have overcome this by making walking compulsory in all games, running counting as a foul and being penalized. On the whole our experience has been that most sprains have occurred during off-duty periods when the patient has not been supervised and has been taking liberties with his limb.

Once a week the power of the quadriceps is estimated by weight and pulley. Originally we treated these cases by daily weight-and-pulley exercises. We found, however, that many men complained of pain under the patellar ligament when doing the exercises, and that pain, rather than a weakened quadriceps, seemed to be responsible for delay in improvement. We have now discarded the routine use of pulley exercises in meniscectomy cases, and as yet have not had reason to regret this step. The weekly pulley exercise is retained as a measure of quadriceps power.

The patient is considered fit for discharge when the quadriceps of the operated leg has regained power to 75% of the good leg, as estimated by weight and pulley, the patient having a full range of painless movement and full confidence in the knee.

The rehabilitation annexe is also used as a diagnostic centre for obscure knee-joint injuries. The difficulties of accurate diagnosis in knee-joint injuries in Service patients have been amply stressed. Any patient admitted to the hospital with a provisional diagnosis of I.D.K. in whom a definite diagnosis cannot be established is transferred to the rehabilitation annexe. Here he quickly progresses to the final class doing full P.T. and games. During this treatment one of two things usually occurs: the knee may give way in a typical manner and the diagnosis become apparent, or the patient may be rehabilitated with a painless knee in which he has full confidence. A few cases do not respond in either of these two ways; they still have painful knees, with a feeling of insecurity and a weak quadriceps. Some are undoubtedly cases of early arthritis, and are referred to a medical board.

Occupational Therapy

A large hut has been equipped for occupational therapy at the parent hospital. The department is staffed by technicians trained in the various handicrafts, and the work is supervised by a medical officer and the senior masseuse. This enables the work of the occupational-therapy and physiotherapy departments to be co-ordinated satisfactorily. We agree with Watson-Jones (1942) that a remedial workshop is not a rehabilitation centre, and in the treatment of Service injuries occupational therapy is only an adjunct to more active rehabilitation. We have found it particularly useful in the early mobilization of stiff joints—e.g., fingers and shoulders. In patients so severely injured as to be discharged from the Services—in which more energetic treatment is ruled out by the disability—we have found occupational therapy of considerable value. In reconstructional surgery of the severely injured it will no doubt prove a useful preliminary to the later vocational training.

Medical Staff

The work in the occupational-therapy department at the auxiliary hospitals and at the rehabilitation annexe is supervised by one member of the staff who has taken a particular interest in it and who sees the patients regularly. We feel that in the absence of a full-time rehabilitation officer this supervision is best done by one of the surgical team, who is thereby enabled to establish continuity of treatment. We feel also that in some ways he has an advantage over the full-time rehabilitation officer, for the rôle of the medical man in rehabilitation, apart from supervising and detailing treatment, is largely that of a medical whip and a mental poultice. The patients are, on the whole, more willing to be spurred on by the surgeon who has already had them under his care. The work requires patience, tact, and driving power, and one is more able to drive up to the patient's limit if one has already gained his confidence and also has a clear conception of the pathology of each case. No doubt the time will come when all rehabilitation will be carried out under the care of full-time officers; but we feel that their work should be closely co-ordinated and supervised by those responsible for the previous surgical treatment.

This development in rehabilitation work has been made practicable by the co-operation of the Regional Hospital Officer, Major-Gen. R. W. D. Leslie, and thanks are due to him and his deputy, Dr. A. Alan Forty, for their willingness to give every assistance in the establishment and equipment of the rehabilitation annexe and in the co-ordination of the work in the auxiliary hospitals.

A UNIVERSAL APPARATUS FOR PERORAL INTRATRACHEAL ANAESTHESIA

BY

GRAHAM HUMBY, M.R.C.S.

E.M.S. Plastic Surgeon; E.M.S. Surgeon to the Hospital for Sick Children

WITH THE ANAESTHETIST'S POINT OF VIEW

BY

MARGARET HAWKSLEY, M.B.

E.M.S. Anaesthetist, Base Hospital, Hemel Hempstead

There is no branch of surgery in which the surgeon is more intimately associated with the anaesthetist than in oral surgery, and more particularly cleft-palate operations; with this excuse I take the liberty of expressing my ideas on the subject.

Intratracheal anaesthesia for oral surgery is unsatisfactory, because there is no apparatus universally applicable to the wide variety of common operations. What are the desiderata for a peroral-intratracheal anaesthetic in an infant who may have to be anaesthetized for an hour or so? Infants are quoted because they are the most difficult subjects to anaesthetize, and it was upon 400 hare-lip and cleft-palate cases that the universal apparatus has been evolved.

Desiderata

Mechanical.—(1) It must be possible to use the apparatus with or without a Davis gag—i.e., for hare-lip or cleft-palate cases. (2) It must stay in position without packing once it is introduced. (3) It must not be kinked or squashed. (4) The intratracheal portion must be of rubber to produce the minimum tracheitis or laryngitis. (5) It must be easily sterilized. (6) The apparatus must be able to fit snugly into the gag without pressing it on the lower lip.

Physiological.—(1) An infant must be kept in the second stage of anaesthesia indefinitely. Contrary to the usual teaching, gas-and-oxygen is the perfect anaesthetic in infants so long as the percentage of the gases is controlled. All the cases had nitrous oxide after induction, and among them were cases of protruding premaxilla hare-lip in infants 1 month old in which the premaxilla was replaced in addition to the bilateral lip repair—a long and shock-producing operation. There was no operative or anaesthetic mortality. (2) Carbon dioxide must be expelled as near to the lungs as is possible because infants will not tolerate a raised alveolar carbon dioxide percentage. (3) No positive pressure or rebreathing must be allowed in infants because of the coincident raised blood pressure and respiration depth.

Description of the Apparatus

The universal apparatus to be described fulfils these conditions. It is made in two sizes, for adults and children respectively, and consists of an intratracheal part (Fig. 1, A) and a chin-piece (Fig. 1, B).

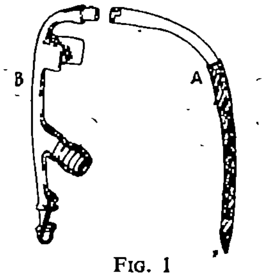

Fig. 1

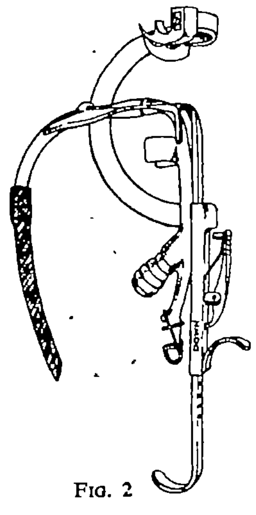

Fig. 2

Intratracheal Part.—This consists of a rubber tube pressed firmly on to the serrated end of a curved metal tube. Three sizes and curves of the metal portion are made for children, and they correspond to sizes 00, 0, and 1 Magill nasal tubes. The rubber portions are 2¼ in., 2½ in., and 3 in. long respectively, and are used on children from 1 month to 4 years old. The adult intratracheal sizes are made to demand; the chin-piece corresponds to a No. 10 Magill. The intratracheal portion is passed by means of a laryngoscope and united to the chin-piece by a bayonet joint which works through a right-angle, ensuring that it cannot be lost down the throat.

Chin-piece.—The inspiratory opening is placed under the chin at an angle to the main tube, promoting easy inspiration; it will be noticed that the inspiratory lumen is as large as the largest intratracheal tube. The expiratory opening is guarded by a thin rubber valve. In the adult model the valve can be removed and replaced by a length of rubber tubing or a metal cap should rebreathing or a closed circuit be desired. A curved chin-strap rests below the lower lip to prevent the apparatus from rotating, and this is fixed to the chin by adhesive strapping.

Fig. 2 shows how snugly the apparatus fits a Davis type gag: the only alteration necessary for the apparatus to fit a standard gag is the addition of a slot in the tongue depressor to allow the metal part of the tube to lie out of the way.

THE ANAESTHETIST'S POINT OF VIEW

The standard Boyle's gas-oxygen apparatus, as supplied by the Ministry of Health to Emergency Medical Service hospitals, has been used with this apparatus. The only expiratory valve employed is that which is attached to the chin-piece and already described.

Induction.—The infant, premedicated only with atropine, is induced on the operating table, the agent of choice being vinyl ether on an open mask. This provides a quick induction with ready relaxation of the jaw, the required depth being quickly reached and as quickly recovered from, and the laryngeal spasm so common with ethyl chloride is very rarely encountered.

Intubation.—The passing of the tube may present a few difficulties, particularly in infants of 4 weeks or so. A small-size laryngoscope is used, and the tube is passed via the mouth by direct vision. In adults it is not always necessary actually to see the vocal cords when passing the tube if the epiglottis and oesophagus are clearly in view, but in the infant it is essential to make sure that the tip of the tube passes through the vocal cords, otherwise it may slip behind the larynx and down the oesophagus. To bring the cords clearly into view the shoulders are first raised by an assistant and then, when the epiglottis is seen, gently replaced on the table. It is advisable not to touch the epiglottis with the laryngoscope, as this may result in immediate spasm of the vocal cords. Attempts to pass the tube should not be made until conditions for so doing are at their best; second and third attempts are more difficult, and are harmful to the child. The infant should be in the third stage of anaesthesia, breathing quietly and easily; if the plane is not deep enough laryngeal spasm will probably be encountered, preventing passage of the tube and necessitating a second attempt.

Maintenance.—The gas and oxygen are turned on just beforehand and the apparatus laid to hand ready connected except for the bayonet joint. Once the tube is *in situ* and connected, gas and oxygen and sometimes two or three whiffs of ether only are required. The rate of flow is about half the rate usually necessary with ordinary intubation and expiratory valve. For a child 1 year old 2 litres of N_2O and 1/2 litre of O_2 per minute are necessary. The anaesthesia lightens rapidly to the second stage with reappearance of the pharyngeal reflex, which the surgeon can evoke when he wishes to assess the adequacy of his operation. As the last stitches are being inserted the gas is turned off, and when the tube is removed the anaesthesia is light enough for the child to cry and cough.

Comparison with Other Methods

Simple Oral Anaesthesia.—Comparison with other methods of anaesthesia, such as a hooked tube in the mouth or an attachment to tongue forceps delivering ether and oxygen, shows very obvious advantages. Without an endotracheal tube it is impossible to keep the child on a light even plane of anaesthesia. Either the child is lightly anaesthetized and by its gagging and moving impedes the surgeon or else it is deeply under, with consequent disadvantages to itself and greater risk of post-operative complications, formerly so common in this branch of surgery.

Magill Armoured Tube.—Advantages of the apparatus over the Magill unkinkable endotracheal tube are: (1) It stays in place without a gag, a gag being unnecessary in the case of hare-lip operations, as the metal portion extends over the back of the tongue. The Magill tube is inclined to ride up even when packed, because of the metal spiral it contains. (2) It cannot wear out if used with a gag, as only the metal portion comes into contact with it. Fresh rubber ends can be fitted each time if necessary, as it is inadvisable to use tubes after they have become softened by boiling. (3) A fully controlled anaesthesia is obtained. The large-bore inlet allows gases to be drawn into the lungs as required by the child's respirations and exhaled easily by means of the simple valve close to the face. This is not the case with the Magill tube, in which gases under slight positive pressure are supplied by the small-bore inlet tube, no bag or expiratory valve being used: incidentally, omission of a bag causes a waste of gas. Also, the funnel-shaped expiratory opening of the armoured tube, perhaps elongated with rubber tubing, may upset the gas-oxygen percentages should the child increase its inspiratory effort from external causes. (4) Actual passing of the tube is slightly easier owing to its curve; with this apparatus the anaesthetist's right hand is at the side of the mouth and therefore does not obstruct the view of the glottis.

Magill Nasal Tube.—This interferes with the contraction of the nasopharyngeal sphincter and any manipulations that may be necessary with the nasal mucosa. If a rubber tube is used orally with a gag it is apt to be squashed or kinked by the tongue depressor either on the tongue or against the posterior pharyngeal wall.

Disadvantages of the Apparatus.—The disadvantages should be mentioned. The apparatus consists of three portions, and it may be argued that these could come apart; but if that possibility is borne in mind and the rubber tube is pushed on up to the upper limit of the serrations this should never happen: it is important to fit the right-sized rubber to the right-sized metal. In an earlier model the bayonet joint between the two main portions occasionally slipped undone, but the improved joint working through a right-angle precludes this possibility.

Comment

To sum up, this apparatus provides an even, light, controlled gas-oxygen anaesthesia. Once the apparatus is in position, a procedure which should take altogether from five to seven minutes, neither anaesthetist nor surgeon has any further worry: the child is round immediately the operation is finished, and there are no post-operative complications due to the anaesthetic. Although originally designed for use in children it is evident that the apparatus will be a valuable addition to the anaesthetist's outfit for all operations on the head and neck in adults.

Those who are interested in the practical application of the apparatus (made by Down Bros.) are welcomed at Hemel Hempstead Base Hospital on Tuesdays at 9.30 a.m.

IMPETIGO CONTAGIOSA IN THE SERVICES

WITH SPECIAL REFERENCE TO ITS TREATMENT WITH SULPHATHIAZOLE

BY

G. A. GRANT PETERKIN, M.B., B.Ch.
Major, R.A.M.C.: Dermatological Specialist; formerly Assistant Physician, Skin Department, Royal Infirmary, Edinburgh

AND

E. COLIN JONES, M.B., B.S.
Lieut., R.A.M.C.: Graded Dermatologist

The treatment of dermatological cases in the Services is in many respects more satisfactory than in civil life, as the average contagious skin case, to prevent further infection in the unit, is admitted to hospital and up-to-date methods are available. Compared with those in civil practice, the cases of impetigo treated in the Services are on the average more severe, and a certain number proved resistant to treatment, many healing slowly, sometimes because of a persistent folliculitis and sometimes because of tiny re-inoculations, causing small oozing lesions.

In a military hospital entirely for dermatological patients 1,432 cases were admitted during the five months from May 14 to Oct. 14, and 396 of these were impetigo, so that there was ample opportunity of studying the action of drugs on this disease. A number of types were encountered, which for clinical purposes might be divided into the following groups: (1) Extensive, with excessive crusting (i.e., often the whole face affected). (2) Extensive, with moderate crusting. (3) Extensive, with small weeping crusted lesions (i.e., up to 1 cm. diameter). (4) Mild—one or two areas. (5) Mixed: excessive crusts (indicating a streptococcal origin), with superficial vesicular lesions and perhaps folliculitis (staphylococcal). (6) Staphylococcal type (i.e., initial small bullae), followed by superficial crusting with slight inflammation, peripheral vesiculation, and residual pigmentation (Roxburgh, 1941). (7) A type of seborrhoeic skin characterized by small superficial erosions, and often associated with a retro-auricular dermatitis.

Differential Diagnosis

The differential diagnosis proved to vary somewhat from that in civil practice, and the following conditions seemed to be easily mistaken for impetigo.

1. *Respirator Dermatitis.*—Every case of this was referred as an impetigo, as the cheeks, chin, and brow were covered with golden-yellow crusts with marked exudation; the typical distribution, especially the involvement of the submental region, and the sharp demarcation of the lesions, followed by a positive patch test, established the diagnosis.

2. *Sycosis.*—The duration of the disease was often alone sufficient to make the diagnosis, without the clinical appearances, but some cases of impetigo of the beard region which had been present for several weeks were tending to drift gradually to a true sycosis.

3. *Herpes Simplex.*—In the crusted stage it was virtually impossible to distinguish this disease from a mild impetigo if an intelligent history was not obtainable. There seemed no doubt that some cases of extensive impetigo had begun as an infection of the original herpes.

4. *Seborrhoeic Dermatitis.*—This disease, especially seborrhoeic eczema affecting the scalp and ears, was often labelled impetigo, though it is difficult to draw a dividing line between the diseases in some cases.

5. *Hutchinson's Summer Prurigo.*—The few cases seen were referred for admission as cases either of impetigo or of respirator dermatitis.

6. *Tinea Circinata.*—Circinata impetigo was occasionally thought to be a tinea circinata of the face.

7. *Insect Bites.*—One or two patients with a bullous reaction to insect bites were sent in as cases of bullous impetigo.

Treatment

The routine treatment for impetigo contagiosa was 2% aqueous solution of gentian violet painted on gently night and morning, with a bland grease such as 1% ichthyol paste, zinc cream, or soft paraffin, applied as required to prevent excessive drying of the skin with the paint and to help to soften crusts. It was found that the pure "viola crystallina" was much better than the commercial gentian violet. Among other preparations used was ung. quinolor co. (Squibb) or the Army issue of ung. benzoylis peroxidi, which proved to be excellent, especially for the subacute type with folliculitis; while sulphanilamide, sulphapyridine, sulphathiazole, sodium sulphathiazole, sulphadiazine, and sulphamethazine were also used.

The effect of sulphanilamide and sulphapyridine locally was sometimes brilliant but often disappointing. Sodium sulphathiazole, sulphadiazine, and sulphamethazine were very similar in action, the crusts gradually disappearing, but rapid and complete cure was not often obtained. Sulphathiazole undoubtedly proved to be the drug of choice, and results were obtained which seemed to indicate that it should be used in practically every case of impetigo.

The average stay in hospital for all cases of impetigo, no matter how treated, was 14.6 days; during the period May 15 to Aug. 27, 1942, 273 cases of impetigo contagiosa were admitted. Of these, 120 were treated with sulphathiazole in a water-miscible cream or a starch and zinc oxide paste, and these cases are shown below in more detailed analysis. Altogether 242 cases of impetigo have been treated in the hospital with this drug during the past 6 months. It was found that sulphathiazole was economical in use, for many cases required less than half an ounce of the cream or paste to complete a cure, though in the severer cases more than an ounce had to be employed. Application was a very simple matter—an important point when the treatment is more widely used. The preparation was smeared gently night and morning on the affected areas and the adjacent healthy skin. It was not necessary to remove crusts in any way, as they dried up and disappeared completely in two or three days. This obviated any risk of the rough removal of crusts by forceps or oil, which so often leads to trouble. Patients were advised to shave every day (the razor being sterilized daily in antiseptic), but were told to avoid any tender or badly crusted area. They were allowed to wash their face with plain soap and water, drying very gently with the towel. The effect of the treatment was clearly shown by the number of men who asked hopefully if they might have this form of treatment after they saw the dramatic results in other patients.

To test the efficiency of sulphathiazole, various strengths were employed: 2½%, 5%, and 10% in a water-miscible cream, and, as a contrast, 5% in paste made with 15% zinc oxide and 15% starch. Of the 120 cases of various types of the disease 27 were not cured by sulphathiazole, 17 of these being treated by the 2½% cream, which evidently was too low a concentration of the drug. The 93 cures were obtained in an average time of 6.8 days, which compares very favourably with the average stay of impetigo cases in the hospital (14.6 days). All cases treated and not cured with the 2½% cream tended to clear up to some extent, and the heaped-up crusts rapidly disappeared, but there remained either an obstinate folliculitis or tiny oozing patches with slight yellow crusts, both of which were resistant to treatment. From this it seemed that a 2½% concentration was quite sufficient to cause the disappearance of all streptococcal lesions, but that the staphylococcal infection was apparently unaffected.

Of the 95 cases treated with the 5% and 10%, 10 were not cured, 7 of these being of the superficial staphylococcal type with very little crusting, and 3 of the patients were men with a seborrhoeic dermatitis of the flexural type. The 7 cases of staphylococcal type responded quickly to 2% gentian violet, while the 3 of seborrhoeic nature healed well on ung. benzoylis peroxidi.

Analysis of Cases

1. 10% Sulphathiazole in Cream

Patients treated	19
Patients not cured	1
Patients cured	18
Average rate of cure for 18 patients	7.9 days

2. 5% Sulphathiazole in Cream

Patients treated	30
Patients not cured	3
Patients cured	27
Average rate of cure for 27 patients	6.11 days

3 2½% Sulphathiazole in Cream

Patients treated	25
Patients not cured	17
Patients cured	8
Average rate of cure for 8 patients	4.77 days

4. 5% Sulphathiazole in 15% Starch and 15% Zinc Oxide Paste

Patients treated	46
Patients not cured	6
Patients cured	40
Average rate of cure for 40 patients	6.5 days

5. 5% Sulphadiazine in Paste

Patients treated	20
Patients not cured	14
Patients cured	6
Average rate of cure for 6 patients	12.3 days

Discussion

These results are in accord with those published in the U.S.A. by Sams and Caplands (1941), who treated 53 cases with sulphathiazole ointment in strengths of 5 to 25% and cured their cases in 4 to 10 days, with an average of one week. Also in the U.S.A., Winer and Strakosch (1942), using 5% sulphathiazole in a water-and-oil emulsion, treated 60 children, the time of cure being 4 to 10 days; while Steigman (1942), treating 51 children—most with impetigo following scabies—found that 5% sulphathiazole in paraff. moll. flav. healed them in 4 to 5 days. It is for several reasons somewhat difficult to compare the results of treatment in children with those of treatment in adults, the most important reason being the almost invariable involvement of the beard in adult males, so that shaving is an additional problem and hazard, despite sterilization of shaving appliances. Writing on impetigo in the Services, Thomson (1942) states: "The main point is the fact that all these cases on admission to hospital are of an extremely severe nature. There seems to be little doubt that, once the early stage of the disease has passed, the virulence of the organisms is so high that treatment is rendered extremely difficult. We are still left with the undoubted fact that these patients do not react easily or well to treatment."

No toxic results were observed in the 120 cases reviewed, but 3 patients treated with the drug have since developed a light-sensitivity similar to the reaction of the skin noticed in some cases treated with other members of the sulphonamide series—i.e., the areas treated became oedematous, erythematous, and crusted. This reaction soon settled down with shielding from the light, rest in bed, and the use of a soothing application such as zinc cream. Cases of ecthyma and early infective dermatitis healed well with sulphathiazole locally, but no real or lasting benefit was obtained from its use in sycosis, pustular acne, or infectious eczematoid dermatitis.

Summary and Conclusions

Sulphathiazole seems to be the drug of choice in the local treatment of impetigo.

Of 120 cases analysed, 93 were cured in an average time of 6.8 days, which compares well with the average length of stay in hospital of 14.6 days for impetigo cases.

The vehicle used for the drug seemed to make little difference to the healing rate of the skin: cases treated with the 5% paste healed in 6.5 days and those with the 5% cream in 6.11 days.

Results obtained with 5% concentration were better than those with 2½% and compared very favourably with results from 10%.

Sulphadiazine and sulphamethazine were used in a number of cases, but results were disappointing.

Sodium sulphathiazole (5% cream) gave somewhat erratic results, but was definitely better than sulphadiazine and sulphamethazine.

Quick healing was also obtained with sulphathiazole in ecthyma and early infective dermatitis, but results were disappointing in infectious eczematoid dermatitis, acne vulgaris, and sycosis.

We must express our indebtedness to Dr. Robert Forgan, medical consultant, Pharmaceutical Specialities (May and Baker) Ltd., for his kindness in supplying generous quantities of sulphathiazole.

Medical Memoranda

A Persistent Brow Presentation

The following may be considered of interest as the case record of an unusual condition.

CASE HISTORY

A primipara aged 27, living at a remote farm, began with pains on July 13 and had a good "show." Abdominal examination was difficult on account of a muscular abdominal wall, but it was ascertained that the presentation was a vertex. Per vaginam the os showed no dilatation, but the head was felt through the fornices to be in the right occipito-posterior position. The pelvic measurements were normal. The pains were infrequent and the patient continued about her household duties until July 17, when she was seen again. The os now admitted a finger-tip. Matters remained in this state until July 20, when, as sleep was being interrupted by the occasional pains, 1/4 gr. of morphine was given. After five hours' sound rest, pains began in earnest about 3 a.m. on the 21st, the membranes ruptured at 3.30 a.m., and uterine contractions were strong and regular all day. At 3 p.m. the midwife reported that the head was visible, but in spite of strong pains was not advancing. Vaginal examination at 3.30 p.m. proved the visible portion to be oedematous scalp, the head being arrested in mid-pelvis.

A more detailed examination under light anaesthesia showed a brow presentation in the left anterior position. The frontal suture led the examining fingers to the prominent supra-orbital ridges, and beyond these the nose could just be reached. A gentle attempt was made to push the brow upwards and so convert the presentation to an occiput, but this failed, and it was decided to make a more determined effort with the help of an anaesthetist. By 6 p.m., under deep chloroform anaesthesia, a hand was introduced into the vagina and the head pushed upwards; the fingers were gently insinuated between the infant's face and back of the symphysis pubis until their tips were beyond the chin. The finger-tips were then hooked over the chin and traction exerted. The position changed with surprising ease into a face presentation, in the left mento-anterior position, and forceps were applied. The change of position completely altered the situation. With very slight traction the chin descended and turned to the front, the forceps being allowed to turn with the face. Further moderate traction delivered the chin, and the occiput slipped suddenly over the perineum. The chest and legs followed easily, and the placenta came away spontaneously ten minutes later while a first-degree tear of the perineum was being sutured.

The child was a male of 7¼ lb.; he had a marked caput over the frontal bones, and the face and lips were slightly swollen. He was in a state of mild shock, but began to breathe without intervention and was crying lustily half an hour later. One hour after delivery the mother was taking a light meal; the uterus was firmly contracted and the pulse 60 a minute. Convalescence was uninterrupted except for difficulty of micturition the next day, which required the passage of a catheter.

COMMENT

Although brow presentation probably occurs fairly often as an early transition stage in face presentations, it is recognized as a state of unstable equilibrium, and it is difficult to see how it can become persistent. In the case under consideration the face was pressed firmly against the back of the symphysis, with the chin above and the supra-orbital ridges and nose below that bone. Each uterine contraction caused a slight flexion by depression of the occiput, which only resulted in pushing the face more firmly against the symphysis. Complete flexion was prevented by the nose and supra-orbital ridges, which had passed below the symphysis and were unable to retrace the path of descent. Likewise, when the large occipito-mental diameter occupies the cavity of the pelvis, extension to a face presentation is prevented, as the face is pressed against the posterior surface of the symphysis pubis and the prominent bony chin cannot find room to slip down behind.

It appears then in a brow presentation, with a pelvis and head of normal size, that if the position does not rectify itself before the nose and supra-orbital ridges have passed below the symphysis, simple mechanical considerations afterwards prevent any change in the position.

Reviews

THE VITAMINS IN MEDICINE

The Vitamins in Medicine. By Franklin Bicknell, D.M., M.R.C.P., and Frederick Prescott, M.Sc., Ph.D., A.I.C., M.R.C.S. (Pp. 662; illustrated. 45s.) London: William Heinemann. 1942.

It is often more difficult to do justice to a good book than to find fault with a poor one, and *The Vitamins in Medicine* is decidedly good. It contains ten chapters, devoted respectively to vitamin A, the vitamin B complex (including vitamin H (biotin), adenylic acid, pantothenic acid, vitamin B_6, and various other factors more or less well defined—e.g., choline, *p*-aminobenzoic acid, vitamins M, L_1 and L_2, U, bios, etc.), vitamin B_1, riboflavin, nicotinic acid, vitamin C, vitamin D, vitamin E, vitamin K, and vitamin P. References numbering in all more than 3,000 are given at the end of each chapter. The photographs of patients and structures of tissues have been very well reproduced. For many of them the country or nation to which the patient belonged is stated, indicating usefully that the people of Britain are not quite so free from gross vitamin deficiencies as they are sometimes supposed to be. The chemistry of each vitamin has been treated fully enough to help those readers primarily interested in the physiological and clinical aspects of the subject. One slip was detected: pure vitamin A has not been synthesized—only formed in very minute yield and not purified. The biological standardization of the vitamins is clearly and briefly described. Tables of the vitamin content of various common foods are given in each chapter.

Human requirements of each of the vitamins at different ages, in health and disease, and in relation to special conditions are dealt with by summarizing the findings of different workers and their hypotheses to account for these findings. Methods for detecting partial deficiencies of the vitamins in human beings are described and discussed critically, and typical cases of severe deficiency are depicted by means of photographs of the affected parts and, where possible, by photomicrographs of the affected tissues. The chief diseases that are thought to be due to a lack of vitamin A are toadskin or phrynoderma (probably the same as shark-skin, keratosis pilaris, ichthyosis follicularis, lichen pilaris, lichen spinulosus, and Darier's disease), impairment of dark-adaptation, xerophthalmia, Bitot's spots, asthenopia, lathyrism, etc. There is much conflicting evidence of the effect of vitamin B_6 therapy on cases of muscular atrophy and Parkinsonism. Beriberi is treated at some length, and also the general effects of a deficiency of vitamin B_1 on the nervous system, cardiovascular system, and gastro-intestinal tract. The variety of conditions improved by giving vitamin B_1 is almost astonishing. Results of vitamin therapy are not always the same, and it should be remembered that a diet may be lacking in one or many factors. One clinician may clear up the condition with the missing factor, another may have to supply several factors —e.g., trench mouth seems to require both riboflavin and nicotinic acid to relieve it, and one patient's diet may lack one of these and another's may lack the other.

Apparently many more cases of pellagra have been diagnosed in this country since the cure for it has become available. Vitamin C as a cure for scurvy seemed simple until vitamin P was discovered, but other functions of vitamin C have also been discovered—e.g., in the healing of wounds (and before and after operations), in overcoming various infections, in certain detoxicating processes in the body, etc. Pure ascorbic acid is available and cheap, and apparently never does harm even if taken in excess. The relation of vitamin D to calcification, tooth formation, the endocrine glands, the blood, and infection is discussed at some length, as well as its use in the bleeding tendency in jaundice, lead and radium poisoning, healing of fractures, arthritis, and certain skin diseases.

Evidence is quoted for advising caution against overdosage. The relation of vitamin E to growth, muscular dystrophy, and nervous degeneration is also dealt with. The evidence of any human requirement for vitamin E is very conflicting. The part played by vitamin K in animal (and human) processes as an antihaemorrhagic factor is generally accepted, and most doctors now believe in vitamin P as a factor in maintaining capillary resistance.

ILLUSTRATIONS OF SURGICAL TECHNIQUE

Illustrations of Surgical Treatment: Instruments and Appliances. By Eric L. Farquharson, M.D., F.R.C.S.Ed.; Major, R.A.M.C. With a foreword by Sir John Fraser, M.D., Ch.M., F.R.C.S.Ed. Second edition. (Pp. 392. 25s., plus 7d. postage.) Edinburgh: E. and S. Livingstone. 1942.

The popularity of what may be termed the pictorial type of medical book is now established, and it is a method of presentation particularly suited to so practical a subject as surgical technique. It is said that the greater number of people are "visualists"; if this is so, the majority are catered for very fully by this new tendency. But even the "aurist" could not fail to gain information, for most of these books have an interesting text accompanying the illustrations, which makes them as clear as a practical demonstration.

The new (second) edition of *Illustrations of Surgical Treatment,* by Eric Farquharson, is a good example of all this. For the most part the book concerns itself with the treatment of fractures; the detailed photographs, of exceptionally good quality, of cases under treatment and of the appliances used are so complete that it would seem that the instruction provided is almost as good as could be gained from a personal attendance at fracture clinics over a long period. The methods described are usually orthodox, but here and there the author's inventive ingenuity is displayed in the devising of special methods of splinting or new appliances.

This part of the work, together with a short section on infusion and transfusion, occupies over 250 pages. The remaining part consists of illustrations of surgical instruments and appliances. We find this portion less interesting, since it appears to be but a summary of the surgical instrument makers' catalogues, while the occasional short descriptions are too scanty to be of any real value. There is also some redundancy: Mayo's goitre retractor, for instance, is illustrated no fewer than three times. The student up for his "exams," however, may find it a rapid means of revising the names of the commoner instruments. The quick call for a second edition is sufficient indication that the book is meeting a demand; it is certainly one which can be recommended.

PERSONAL AND COMMUNITY HYGIENE

Personal and Community Health. By C. E. Turner, A.M., Sc.D., Dr.P.H. Sixth edition. (Pp. 642. 18s.) London: Henry Kimpton. 1942.

The sixth edition of Prof. Turner's *Personal and Community Health* continues to qualify for our commendation of an earlier edition. It is a "compendious and most readable" presentation of the subject with which it deals. Under the title "Personal Health" the problem of posture receives attention. Deforming bone diseases excepted, posture is held to be simply a question of muscular balance. Where the balance is awry the muscles should be strengthened by appropriate exercises. Suitable postures are pictured for standing, bending, and sitting. A correct posture, in the author's view, is a personal asset; it displays alertness in men and grace in women, and in both reveals training and helps efficiency. Under the title "Community Health" reference is made to the diligence of life assurance companies in the United States to promote, by education and otherwise, the health of their policy-holders. In this connexion the author attaches importance to the annual medical overhaul, for which purpose, as well as for treatment, the services of a competent physician should be sought. Such a person may be recognized by his good medical degree, his training in a first-class hospital, and his high ethical code, sustained by which he does not advertise himself or offer secret methods of cure, or flit from place to place after a brief sojourn in each in order to elude the wrath of his mistreated patients. A feature of the book is the reproduction of the Children's Charter, enunciating the standards for child welfare set by the Third White House Conference. The illustrations are excellent, excepting those of insects, which might have been better chosen.

Notes on Books

Two years ago we welcomed the appearance of Sir ARTHUR HURST'S *Medical Diseases of War* in its new form, the success of which is shown by the publication of a third edition (Edward Arnold, 21s.). It has been brought up to date by new chapters on typhus and diphtheria, both of which diseases have brought new problems. There are new bacteriological sections, and fresh information on such topical subjects as cerebral concussion, scabies, mustard gas, and the treatment of bacillary dysentery with sulphaguanidine. It is the best compendium of war medicine that we know.

Preparations and Appliances

SAFETY DEVICE FOR SUCTION PUMP USED FOR OBTAINING BLOOD FOR TRANSFUSION

Dr. E. M. WATSON, Professor of Pathological Chemistry, University of Western Ontario Medical School, London, Canada, writes:

The withdrawal of venous blood for the purpose of transfusion is commonly regarded as a simple and harmless procedure; nevertheless a fatal case of air embolism involving a blood donor was recorded in the *British Medical Journal* (1941, **2**, 311). The disaster was the result of the electric rotary pump which was used to create suction reversing its action when the current was switched off. While this may be an isolated incident, it serves as a tragic example of what may happen when a mechanical suction pump is employed for the taking of blood in the absence of special precautionary measures. The implication is clear in the light of the present need for donors. A pump may be made safe by adopting some simple modification such as the installation of a safety-valve in the suction tube.

In an attempt to comply with the timely warning contained in the above-mentioned article—in effect, that any hospital making use of the rotary suction pump should take steps to have the necessary alterations made in the apparatus—the device described below was constructed.

The main accessory consists essentially of a glass ball-valve interposed in the suction current (Fig. 1). As portrayed in greater detail in Fig. 2, the ball-valve has been fashioned from a piece of clear glass tubing, 10 mm. in diameter, within which is contained a float made from a piece of brown glass rod (A). The expanded pointed end of the float (B) has been ground to fit snugly into a hollow seat formed by a thickening of the wall of the tube (C). In order that the float may remain constantly in its proper upright position, a glass collar (D) and three short arms (E) were incorporated. When the apparatus is in operation the float bobs up and down with the action of the suction pump, but immediately the latter stops the float drops, causing the valve to close tightly; consequently air cannot escape past it toward the donor.

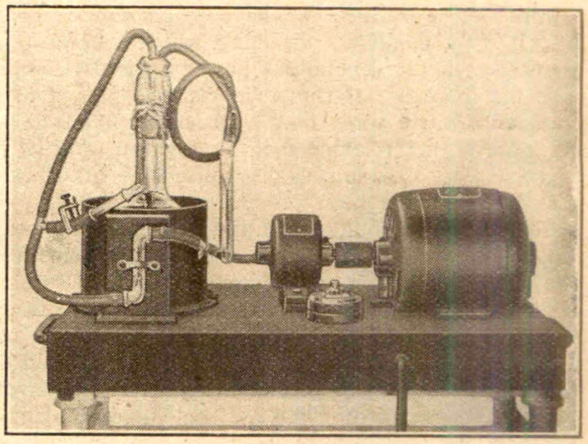

FIG. 1

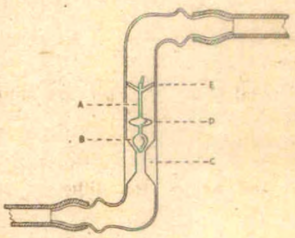

FIG. 2

As additional safeguards, two glass T-tubes are included in the system (Fig. 1). The one proximal to the safety-valve has a small external opening and serves to regulate the degree of suction as well as acting as a by-pass in the event of any back-pressure. The opening of the T-tube distal to the safety-valve contains some loosely packed cotton-wool and is controlled by means of a pinch-cock. After the desired amount of blood has been obtained from a donor the pinch-cock is released and the electric current to the motor switched off. The airtight valve closes, the pressure within and without the flask becomes equalized, and the possibility of air embolism is avoided. The contrivance has been found to work satisfactorily.

The installations described above were made and assembled by Mr. A. Barber of the Department of Pathological Chemistry, University of Western Ontario.

REHABILITATION: THE DUTY OF SOCIAL MEDICINE

New words come into fashion from time to time, and, especially if they are polysyllables, are hailed as descriptions of new things. Even the scientific world, including medicine, is not exempt from the tyranny of the slogan. A current example is the word "rehabilitation." It is not always used with discrimination. Even the Beveridge report (para. 426) speaks of rehabilitation as "a new field of medical activity with great possibilities." The truth is, as Matthew Arnold said of the word "Philistinism," which suddenly became fashionable in his time, we have not had the word before because we have had so much of the thing. It is the name, not the thing, which is new.

Medical men for generations have practised rehabilitation in the sense of returning the disabled patient to his former work or to some new work suited to his diminished capacity, not relaxing their supervision until he has been completely re-established. In several branches of medicine there have been noteworthy movements along these lines. The more humane attitude towards the insane, which began with the abolition of the old system of restraint and has gone on to vast improvements in care and treatment, including occupational therapy, is an example of rehabilitation in a field which might have been considered almost hopeless, and it has been demonstrated that patients discharged from mental hospitals into after-care are by no means unemployable. The village settlements or colonies for the tuberculous, of which Papworth was the first, furnish another example; and the institutions—at Leatherhead, Exeter, Oswestry, and Erskine House, Glasgow—for restoring the disabled and limbless yet another. The Army long since provided physical development centres, convalescent depots, and hospitals for nervous conditions, all closely linked with the Service; and in industry there are the rehabilitation centres at Berry Hill Hall in the Midland coalfield, at the L.M.S. Hospital in the great railway centre at Crewe, and at the Albert Dock Hospital in London, all run by surgeons and by a team familiar with every kind of work in the industries concerned.

It is true, nevertheless, that rehabilitation has lately received a new significance. Members of the medical profession feel increasingly that their obligations extend beyond the recovery of the sick person. They realize how profoundly the convalescent stage may be affected by occupation or prospect of occupation, and how necessary it is for the convalescent to have medical guidance if, on the one hand, he is not to return to work too soon, and, on the other, he is not to delay until he has lost his skill and his heart for the work. As Brigadier Cairns says in the article which we publish in this issue, the new thing in rehabilitation is the very general realization by the medical profession of its responsibility for convalescence and its formal recognition of the part which a patient's personality plays in his readjustment after injury or disease.

Rehabilitation, which in its medical sense has not yet got into the Oxford Dictionary, was first mentioned in relation to co-ordinated efforts to condition the patient's recovery after a fracture, which is the most fertile single cause of permanent disability. It was regarded then as the function primarily of the physiotherapy department, and in a good many minds rehabilitation still means no more than physical medicine. Actually it reaches out far beyond that province and beyond the province of any group of specialists; it brings in occupational therapy, vocational training, and the arousal and maintenance of mental interests. The B.M.A. put forward its ideas on the subject in the report of its Committee on Fractures eight years ago, and developed them further in its evidence before the Departmental Committee on Workmen's Compensation and in a later report on industrial health. It proposed rehabilitation units for temporary light work in which a group of patients would be under the day-by-day personal supervision of a medical man. It was never in mind that there should be detached centres, a sort of distant annex to the factory, directed by non-medical personnel.

The Beveridge report uses a dubious phrase when it says that rehabilitation must be continued from the medical through the "post-medical stage" until the maximum of earning capacity is reached. A good deal depends on the definition of "post-medical"—the word itself is no definition at all. Is it a stage from which medical care is withdrawn, and rehabilitation (or reconditioning, or resettlement, or whatever word is used) is left in charge of industrial instructors, perhaps with the help of a masseuse? It must be in charge of somebody. The patient himself can, and indeed must, co-operate, but he cannot be the overseer of his own rehabilitation. The Tomlinson Committee (the Interdepartmental Committee on Rehabilitation),[1] which makes some wise and bold recommendations, does not use the word "post-medical," but it speaks of post-hospital rehabilitation in which, instead of continuous medical supervision, medical advice will be at call, the presumption being that it will only be called when there is some retrogression in the man's condition. The post-hospital period is expected to bridge the gap between the completion of hospital treatment and the establishment of fitness for such employment as is within reach of the disabled. This reconditioning is to take place at residential centres in various parts of the country, from which in due course the persons concerned will either go back to their old employment or enter upon an educational training course for a new job. But the Tomlinson Committee, enlightened as most of its recommendations are, comes down on the industrial rather than on the medical side of the process. It does not consider that whole-time medical superintendents are necessary at these centres. In other words, the function of medicine in this highly critical field will be consultative rather than supervisory.

The matter is important because the Tomlinson report, overshadowed though it is by the social security proposals, may well result in a very considerable reorganization of industry. The longer the war lasts the greater will be the number of the disabled, and as it is "total" war it is not this time a question only of the crippled soldier, but of dealing with crippled civilians—men, women, and children. No one can predict the final number, which may well be formidable, and to it are constantly being added the victims of mechanized industry and transport and those handicapped by conditions following upon disease or congenital deformity. This is not a matter for charity any more than is the payment of interest on the National Debt. The country must accept the fact that a certain proportion of its citizens are permanently disabled, although in the great majority of cases not to such an extent as to unfit them for some employment, and must consent to any slowing of the tempo of industry or any lessened skill in service which the absorption of these people may involve. The important thing, for the sake of the disabled themselves as well as for the sake of the community, is to readjust them to such work as they can do. It will mean a good deal of fitting, not merely of square or rounded pegs, but of pegs presenting every kind of asymmetry, into holes as appropriate and congenial as possible. In that task—as important as any in the post-war era—it is the medical profession which must take the leading share; and, with great respect to the famous author of the phrase, to talk of a "post-medical stage," meaning a non-medical stage, or even of a post-hospital stage in which the doctor is summoned only when something goes wrong, is to under-estimate some vital factors in the situation.

---

[1] Cmd. 6415. H.M. Stationery Office. (9d.).

The situation at present, of course, is obscured by shortage of labour. There is now next to no unemployment among those who are fit to work at all. We are informed, for instance, that there are actually no deaf persons unemployed unless also incapacitated by age or by some additional infirmity, and it is said that there are no fewer than 340 different occupations which can be followed by the deaf. But it is necessary to envisage a time when normal industrial conditions will return, or perhaps a time of industrial depression and unemployment, when employers will naturally want to select the fit in preference to the unfit for such jobs as are available. Some means must be found for securing that the disabled are not cast on the scrapheap. No doubt much could be done by persuasion and example on the part of Government Departments, local authorities, public utility undertakings, and public-spirited private employers, but this is a national liability, and the voluntary principle will not fill the bill. The Tomlinson Committee has, it seems to us rightly, rejected the idea of subsidies to employers for taking disabled men. The alternative is a statutory obligation on employers to accept a quota of disabled, and the setting up of a register of handicapped persons and a schedule of occupations which will primarily, though not exclusively, be reserved for them. If such occupations as lift attendants and messengers are mentioned, it is because those are the first which come to mind. Actually such a schedule might be indefinitely extended, but to over-extend it, of course, might have grotesque results. Its construction will need the exercise of something like genius, but harder problems have been tackled.

The industries of this country are highly diversified: so are the jobs in each industry, and so are their demands on physical capacity. As has often been said, the loss of a finger may be a barrier to one job, whereas another can be done by a person without arms. But the question of fitness for the job goes much deeper than that. It takes cognizance not only of physical defects and their compensations, but of age, temperament, mentality, and social circumstances. An employer may not be greatly impressed by the figures for the Ford works in America, where 10% of those on the pay roll are physically defective and where it has been proved that cripples can earn full wages; he will be anxious about the accident-proneness of these handicapped people whom he is asked to employ, and about their increased susceptibility to fatigue and likely sickness absenteeism. Another factor to be dealt with may be unwillingness on the part of other workers to work with a disabled person. This is said to operate in the case of persons under treatment for tuberculosis; but the rehabilitation of the tuberculous, as also of heart cases, must be dealt with as a separate problem, not on that ground alone but because they need specially sheltered conditions.

In all these readjustments and adaptations the major problem is a medical or a medico-psychological one. After the "crooked" have been made straight there are innumerable "rough places" which must be made smooth. It is the understanding medical man, especially if he has studied industrial health, who can best assess the usefulness of his patient, advise on his place in industry, and ensure that his restored capacity is used without detriment to himself and to the best advantage in the field of productive effort.

Physical defectives are often unusually conscientious and reliable persons. The consciousness of one defect makes them use their other powers with special care and alertness. On the other hand, there are defectives who lose themselves in self-pity or fall back on the reflection that because of their disability not much is expected of them. Again, there are people who are uncertain of themselves and need the confidence which only the doctor can impart. In addition to the surgical group of disablements, which are more or less obvious, there are disablements in the medical group which are not so obvious and about which the industrial supervisor or foreman needs to be carefully informed. For all these reasons, rehabilitation, which after all is only treatment as the medical profession understands it, should not be split up into a medical and, after that, a non-medical phase in which the patient will be seen no more by the doctor. The medical man, whether surgeon or physician or general practitioner, must be allowed to treat his case to a conclusion, and the conclusion is the re-establishment of the patient as an economic unit to the full extent of his recovered capacity.

DEMOCRATIC MEDICINE

At this particular moment in the history of medicine it is perhaps as well to recall that the foundations of medical science and medical practice have been laid and built upon by men practising their profession freely, restrained only by the authority of their own consciences and by their freely accepted obligations to professional organizations, corporations, and colleges. Those two great English doctors, William Harvey and Thomas Sydenham, the one a royalist and the other a puritan, made their fundamental contributions to physiology and clinical science as freely practising physicians. John Hunter, Edward Jenner, John Snow, Joseph Lister, James Mackenzie, Richard Bright, Thomas Addison—these men brought their great gifts to fruition in a system of medicine which now appears to have more detractors than advocates. The master builder of the public health service—John Simon—was a surgeon at St. Thomas's Hospital, and he made it a condition that he should continue in this post when he accepted the appointment of Medical Officer to the Privy Council. This is not another way of saying, "What is good enough for my grandfather is good enough for me." It is not to say that the changed times in which we live do not demand a new approach, or new approaches, to the many difficulties that beset the practice of the art and the science of medicine. But those who are eager to pull down the existing structure in the illusion that they are going to build something quite new should perhaps be a little clearer in their own minds just what it is they wish to destroy. Tradition is not a meaningless term, and the tradition of freely accepted obligations to their own profession as well as to the public they serve is a powerful binding force among medical men and productive of great good.

Doctors generally have supported the attack made by Sir William Beveridge on want, idleness, squalor, and ignorance. The Atlantic Charter put the attainment of freedom from want and freedom from fear as objectives of world policy. Medical men are common enough witnesses to the disasters to the individual from fear and from want to see in the removal of these an essential step to the attainment of good health. But these are negative freedoms. Freedom to think, freedom to express thought in speech and in writing without the hindrance of authority, are the necessary conditions of all creative and scientific work. It is well, therefore, to take heed of the warning so cogently voiced by Dr. Geoffrey Bourne in an article published in the *Journal* of February 20. There he reminds us that this freedom of expression is denied by the largest and most powerful local authority in this country—the London County Council. No doctor in the service of the L.C.C. can submit for publication a scientific article, or a letter, unless he has the permission of the Chief Medical Officer to the L.C.C. From time to time we receive for publication letters from medical men employed by local authorities in which anonymity is requested on the grounds that criticism—moderately worded and well based—will offend the authority and so hinder the future promotion of the writer. The good work done by local authority medical services—and especially by the L.C.C. in hospital development—is fully recognized. But this petty censorship is something that should not happen in a world of adult men. It is, as Dr. Bourne points out, the working of an autocratic system, seen in another form in the local authority hospital, where the medical superintendent can impose, for example, his own personal whims of treatment upon the medical officers under his charge. This kind of thing kills initiative, undermines the sense of individual responsibility, and encourages sloth of mind.

"It is my nature," wrote Sydenham, "to think where others read; to ask less whether the world agrees with me than whether I agree with the truth; and to hold cheap the rumour and applause of the multitude." No medical man can work freely and productively if he has always to ask whether a medical administrator agrees with him or not. As opposed to the autocratic system Dr. Bourne sets the democratic system of the voluntary hospital. Again it is well to remind critics of the latter that it has been from the big voluntary teaching hospitals of this country that the main stream of medical research has proceeded. Most of the voluntary hospitals are managed medically by committees composed of members of the medical staff, all on a footing of equality. The control is horizontal, not vertical. There is no medical autocrat with power of veto. The spirit of freedom and independence fostered by such a system permeates the teaching hospital and is handed on generation after generation to the medical students that pass through its gates to practise their profession in the outside world. In this week's correspondence columns Dr. Lindsey Batten persuasively describes what this freedom means in the conduct of general practice.

What Dr. Bourne calls "the democratic system of medical service" is, he believes, "entirely compatible with State control"; and a State Medical Service "on a grand scale" he sees as an inevitable consequence of the implementing of the Beveridge plan. That the medical services of this country are in need of reorganization is widely accepted. That this will to some extent restrict the freedom of the individual doctor is recognized. That the State, working through local bodies, is likely to have a greater say in the conduct of medical practice is inevitable, whether on the basis of a whole-time salaried service or not. Whatever system may evolve, the scientific freedom of the individual doctor must be preserved; without this such things as free choice of doctor are meaningless. In the coming negotiations with the Ministry of Health the vocational safeguards laid down in the draft Interim Report of the Medical Planning Commission must be insisted upon. All along the line of any national comprehensive health service the vocational body must direct and control professional matters; the practising clinician must not be subservient to the administrator; in any professional group medical men must work as free equals. "What advantage," wrote Sydenham's great contemporary, Milton, "is it to be a man over it is to be a boy at school, if we have only escaped the ferula to come under the fescue of an Imprimatur, if serious and elaborate writings, as if they were no more than the theme of a grammar-lad under his pedagogue, must not be allowed without the cursory eyes of a temporising licenser?"

PROPAMIDINE

Propamidine, stilbamidine, and pentamidine are diamidine compounds recently introduced for the treatment of trypanosomiasis and other protozoal infections. With a view to determining whether they are likely also to have any useful antibacterial action A. T. Fuller[1] has recently performed simple *in vitro* tests embracing a long series of similar compounds and a wide range of bacterial species, thus affording a general picture of the relationship between structure and capacity to inhibit bacterial growth. Many of these substances are bacteriostatic in very low concentrations, their action being most marked on Gram-positive cocci, rather less pronounced on anaerobic Gram-positive bacilli, and least on Gram-negative bacilli. No curative effect was obtained by systemic administration on infection by *Strep. pyogenes* in mice. It has been considered that propamidine (4 : 4′-diamidinophenoxypropane dihydrochloride) has the most promising characters as an antiseptic, and its investigation from this point of view has reached the stage not only of *ad hoc* experiment but of clinical trial. W. R. Thrower and F. C. O. Valentine[2] have tested its action under various *in vitro* conditions on staphylococci and haemolytic streptococci. It has a powerful bacteriostatic action on both, but measured in terms of minimum inhibitory concentrations is about four times as effective against *Strep. pyogenes as against Staph. aureus*: as judged by the slide-cell method it is nevertheless somewhat superior to sulphathiazole against staphylococci. Blood appears to diminish its action somewhat, and pus markedly so, the concentrations required to kill these cocci in natural pus being much greater than those in broth. On the other hand, phagocytosis is unaffected by concentrations greater still, and in a strength of 0.1% leucocytes are unaffected, while these two species of organism should be destroyed in any medium. It would be interesting to have further laboratory data on other bacterial species, including observations on the rate of disinfection, the degree of interference with it by various types of added material, and some comparison with other antiseptics, such, for example, as the acridines. In due course some attempt will also doubtless be made to determine what is the nature of the action of propamidine on bacteria

These authors, and those of three succeeding papers, also describe the effects of applying propamidine to infected wounds. It has been used in a concentration of 0.1% in a methyl cellulose base, forming a jelly with which the wound was filled if it formed a cavity; burns and other superficial areas were covered with a thick layer of it, an occlusive dressing of vaseline gauze being applied in either case. The jelly was usually renewed every two days and the treatment continued for ten days in all. The reports are unanimous in describing striking beneficial effects: wounds which had been suppurating, in some cases for long periods, were cleaned up and began to heal. Of various bacteria concerned, streptococci disappeared most rapidly, staphylococci were less easily eradicated, while *Proteus* and *Ps. pyocyanea* were liable to persist in spite of treatment. There is a striking similarity between these accounts and the description by Mitchell and Buttle[3] of their experiences in treating suppurating wounds with proflavine powder. A direct comparison between the two methods in cases suitable for either would be instructive. Meanwhile it is becoming abundantly clear that the antiseptic treatment even of wounds in which infection is firmly established is feasible provided that the antiseptic itself is reasonably non-toxic, and that it is applied in such a way that its action is enabled to persist for several days. Propamidine has joined a company which already includes the sulphonamides, the acridines, penicillin, and gramicidin, and it may be that each will be found to have its particular indications when more is known about how to use them.

SURGERY OF TENDONS

The problems associated with the physiology, pathology, and surgery of tendons continue to cause controversy. Some of these problems have been settled; for example, most surgeons now agree that in grossly contaminated wounds it is wiser to delay suture of divided tendons until the skin has been healed for several weeks. Very satisfactory results follow the repair of most tendons. Except in the hands of Bunnell and his pupils, however, operations on the divided flexors of the fingers are for the most part disappointing. The reasons for this have been, and perhaps still are, obscure. Recent work in this country may soon demonstrate that failure to restore full flexion has been due partly to inability to reproduce adequately the mechanical circumstances in which the flexor tendons of the fingers normally work. Another factor that may determine the final result is the length of time a tendon should be kept at rest after suture. There is need for a more thorough inquiry into the problem of the rate of healing of tendons in man, for it is on a knowledge of this that an intelligent regime of immobilization and mobilization must be founded. Much experimental work has been done already, and none better than that of Mason and Allen[4] on dogs. They set out to determine the rate at which the healing sutured tendon regains its tensile strength, what effect function has on the process of tendon repair, and what is the "holding power" of the tendon for sutures. Briefly their conclusions are as follows. There are three phases in tendon healing, as measured by its tensile strength: (*a*) that of rapid diminution, which lasts about five days; (*b*) that of increase up to a point reached about the sixteenth day; and (*c*) a second phase of increased strength starting between the nineteenth and twenty-first days and continuing for an undetermined period. Function and motion during the first two phases of healing lead to increased reaction and to separation at the suture line. Restricted use—i.e., active contractions with prevention of stretching by appropriate splinting—allowed at the beginning of the third phase (about the third week following suture) produces only a slight increase in reaction, and leads to a rapid increase in tensile strength of the union. Active *unguarded* use, even after three weeks of immobilization, always causes increased reaction and may result in stretching of the suture line. Tendons kept completely immobilized develop excellent gliding sheaths, while early unrestricted use prevents their formation. The "holding power" of the tendon for the suture shows a marked drop below its original power until the fifth day, when it begins to rise, reaching its immediate sutured strength only after fourteen days. The practical lessons to be learnt from these experiments are that complete immobilization is necessary for about three weeks; that active movements, with appropriate precautions to avoid stretching, from that period onwards consolidate the strength of the sutured tendon; and that the use of excessively strong suture material is futile because the tendon will not hold it against movement during the first seven to fourteen days: and even if it did, early mobilization produces sufficient reaction in and around the sutured tendon to prejudice the final result. Though it cannot be assumed that human tendons would react in every way similarly to those of the dog, the findings of Mason and Allen conform sufficiently closely with clinical observations to make them interesting and significant.

CZECHOSLOVAK MEDICAL DEGREES AT OXFORD

The Sheldonian Theatre saw a unique occasion on February 27, when the degree of Medicinae Universae Doctor (Czechoslovakia)—M.U.Dr.—was conferred upon 23 medical students exiled from the Charles University of Prague, the Masaryk University of Brno, and the Komensky University of Bratislava, who had been able to complete their studies in England. The Czechoslovak Government in England had asked the University of Oxford to act as sponsor for these three Czech universities, and with the Vice-Chancellor acting as Rector, the Regius Professor of Medicine as Dean, and the Nuffield Professor of Therapeutics as Promotor, the degrees were conferred in conformity with the legal requirements of the Czechoslovak universities. The students qualified under a special examination conducted by the Examining Board in England of the Royal College of Physicians of London and the Royal College of Surgeons of England. As the General Medical Council have agreed that the M.U.Dr. of Czechoslovakia is registrable under the Temporary Registration Orders, the new graduates will be available to assist the war effort here.

Dr. Benes, President of the Czechoslovak Republic, and Madame Benes were present, and among the large and distinguished gathering were Sir Alfred and Lady Webb-Johnson, Sir Adolphe Abrahams, Sir Henry and Lady Tidy, Lord Simon, Mr. Philip Nichols (British Ambassador to Czechoslovakia), and Dr. Labkowitz (Czechoslovak Ambassador to the Court of St. James). The ceremony, and the representative gathering which attended it, bore witness to the close spirit of co-operation existing between the Czechoslovak Government and ourselves; and it seemed particularly fitting that this co-operation should be manifest in so practical a form. The opening of facilities for scientific study among the refugees in these islands is a clear step towards facilitating reconstruction in the occupied countries after the war. Comradeship in scientific work is, moreover, a true foundation on which to build a Europe united within itself and working towards a common end. All but one of the new graduates appeared in battle dress, and their spokesman voiced the sentiments not only of his comrades but of the whole gathering when he said: "We think with sorrow and pride of our fellow students who died on November 17, 1939, and of the thousands of university teachers and students lingering in the concentration camps because of their loyal and faithful belief in the Czechoslovak Republic and its democratic ideals."

NON-FATAL EFFECTS OF EXHAUST-FUME POISONING

BY

F. W. EURICH, M.D.

Emeritus Professor of Forensic Medicine, University of Leeds;
Consulting Physician, Hythe (Hants) Cottage Hospital

In my experience the effects of acute and subacute poisoning by the fumes from defective motor-cars are not well enough known. Judging from the number of cases seen by me these toxic effects cannot be very rare, and they are likely to occur still more often, as in these war days cars have a longer life on the road than formerly. The effects necessarily vary in severity with the concentration of the fumes when inhaled and with the frequency and duration of exposure to them.

Illustrative Cases

Case 1.—The first case of this kind the true nature of which I recognized was that of a young man in his twenties. He had consulted several practitioners, who all told him that they could not find anything wrong and that it was "just a case of nerves" His complaint was that he felt shaky, a little dizzy at times, and his legs were tired. I, too, found nothing definitely wrong As we sat down to have a talk he asked me: "Do you think that this can throw any light on the trouble? I feel worse after driving my car." Inquiry elicited that the ventilation of his car was defective and exhaust fumes entered it He received the necessary instructions, but no medicine, and made a perfect recovery.

Case 2.—Some time later I was consulted by a master builder, a man in the thirties and of powerful build. He complained of weakness in his limbs; he could no longer carry his little daughter of 2 years upstairs, while ascending the stairs itself was difficult at times. He also complained of headache, but this distressed him less than did the muscular weakness. His troubles came to a head on his arrival at Cardiff after driving in bad weather from Ilkley. The severity of his complaints had varied somewhat in the preceding 10 weeks. On being questioned he said he thought the weakness was greater after driving to his various undertakings in his little car on a wet day, when he had the windows shut, and he admitted that some fumes entered it. On examination his complexion was healthy, and the only abnormality found was weakness of the knee-jerks He was advised either to buy a new car or to drive in all weathers with the windows open. All his complaints disappeared in a fortnight.

The more severe effects of such fumes are illustrated by the following cases:

Case 3.—A lady superintendent of the orthopaedic and massage department of a provincial hospital, aged 31, who had always enjoyed good health, complained of headache one Sunday Next day this became worse and she found that she saw double. At the end of the day a weakness in the lower limbs, which she had noticed earlier, became so great that she needed the help of a companion on her way to the station. She was depressed and easily reduced to tears, quite unlike her usual self. The diplopia, which took place in several directions, could not be explained by the ophthalmic surgeon of the hospital. The ocular defect lasted two months or longer, as did the weakness of the legs. The knee-jerks, faint at first, gradually returned to normal. On inquiry it was found that the room in which she worked was badly overcrowded and ventilated. She therefore worked by an open window, beneath which ambulances and other cars would halt and discharge their fumes. These conditions were altered on resuming her duties, which she was able to do without a return of the trouble. To-day, seven years after her illness, she is in perfect health.

Case 4.—Another case is that of a man in the early sixties who had been taken ill five weeks before I attended him. Tumour of the brain was suspected. When seen by me he was confined to bed, temperature and pulse were normal. The gait was ataxic and there was incoordination of the movements of his upper limbs Ankle-jerks, knee-jerks, and tendon reflexes of the arm could not be elicited. There was diplopia on looking both to the right and to the left. The pupils were equal and reacted to light and accommodation. The disks were normal. Some dizziness was complained of as well as headache. There was no history of vomiting. Against the likelihood of a brain tumour was the history: the onset of the symptoms was too rapid; after a few hours of headache the disordered movement of legs and arms developed, soon followed by the diplopia. When seen by me the incoordination of the legs had already improved slightly. On further questioning it was elicited that the trouble began on the evening of a day on which he had helped to take voters to the booth. For eight hours he had sat in his car. Asked whether the car was well ventilated, he replied: "It stank like hell." I decided that his trouble was due to fumes, and ventured to give a good prognosis. A month or two later I heard that the patient had made an uninterrupted recovery.

Commentary

These cases differ from other forms of poisoning in that chemical and other tests, including the spectroscope, fail to demonstrate the poison because of the small amount of CO present in the blood. The diagnosis must therefore rest upon other evidence. Clinically it is noteworthy that, except in mild cases such as Case 2, the symptoms appear very rapidly—generally within 24 hours—and that, once developed, they do not tend to increase in severity, nor do new symptoms appear in the course of the illness provided there is no further exposure to the fumes. In some cases the action of the pupils is affected. This, too, comes on very rapidly. Disorder of pupil reaction, together with faintness or actual absence of the knee-jerks, may suggest tabes—a diagnosis which I have known to be made—but the rapidity of onset of these symptoms should caution the observer. Sometimes looseness of the bowels occurs in the beginning. Disorders of micturition I have never observed. In none of my patients was poisoning so intense as to affect consciousness, and this may account for the absence of later complications, such as epilepsy, which I have seen in patients found unconscious from CO poisoning. Patients do not always remember immediately on inquiry that the ventilation of their car is defective, but a leading question on the point has never been necessary. The prognosis is apparently good, though convalescence is often protracted.

MALARIA CONTROL IN INDIA

A paper describing the measures taken for the control of malaria in India was read by Sir RICKARD CHRISTOPHERS, F.R.S., in the India and Burma Section of the Royal Society of Arts on Feb. 5. Sir MALCOLM WATSON presided.

Endemic Malaria

The fundamental problem of Indian malaria, said Sir Rickard Christophers, was the endemic malaria of the rural population, which comprised 90% of the inhabitants of India. This occurred in every part of India, with the exception of the high mountains and such fortunate places as Kashmir, where the elevation ruled out the disease. In general, endemic malaria, following the distribution of the rainfall, was lightest in the north-west, and became heavier in the south and east, where there were extensive hyperendemic tracts. Such a problem would tax the resources of the richest and most developed of countries, and India was neither rich nor well developed in the sense of Western Europe. Nevertheless, something was being done, and there was hope that by the new methods of Paris-greening, as well as by education and co-operative action, amelioration might be achieved, at least in some areas.

One form of endemic malaria might be called "irrigation malaria." It was found in the great canal projects of India, projects which were unrivalled in scale anywhere else in the world. Often insufficient precautions were taken to prevent the slow onset of waterlogging with accompanying malaria, but a great deal of attention had been devoted during the last 35 years to the engineering side of malaria control in these regions. Another point about endemic malaria was that, although pre-eminently a rural problem, it was not always confined to the villages. It was a very marked feature in many of the smaller Indian towns of from 20,000 to 100,000 inhabitants, but here the problem was simpler, because educational and other factors could more readily be brought to bear upon it.

On the subject of quinine as a primary measure directed against endemic malaria, Sir Rickard Christophers said that recent work in the Zanzibar Protectorate had led to the conclusion that what was required was that quinine should be made available in such a way that it could be used whenever required by adult or child to tide over acute sickness. This was also the requisite in India, where the remarkable dispensary system offered a channel for the provision of adequate supplies.

Epidemic Malaria

It was characteristic of endemic malaria that, while children suffered from it, adults, thanks to the immunity which they had acquired in childhood, suffered but little. To save the children, therefore, entailed a greater risk in respect of the adults, and the same dilemma appeared in a more sinister form in epidemic malaria. Epidemic malaria was the result of low endemicity, and, the children growing up without immunity, when malaria did come it had the effect of an explosion. Roughly, the major epidemics had occurred, as far back at least as 1876, with a sort of cyclical regularity every eight years or so. It was the last of them, in 1908, which led to the summoning of the Imperial Malaria Conference, and its sequel was a scheme for organized research and preventive action against malaria in India. It was then clearly shown that these cataclysmic events were mainly due to the overflowing of rivers and the flooding of great tracts of country, and that they could be controlled by appropriate engineering measures. It was now 35 years since any further major outbreak had occurred. Colonel Gill, who had made a special study of these epidemics in the Punjab, had shown that by collecting suitable data the locality of the threatened areas could be determined in advance, and quinine and other assistance be brought in readiness.

In India, however, there were many other phases of malaria on a more localized and moderate scale, where direct control was more feasible. Among these was the malaria of cities and large towns and of industrial and engineering projects, such as the tea and jute estates, and of Army cantonments. At the Imperial Malaria Conference in 1910 a central and a number of provincial malaria organizations were formed. The function of the central organization, now the Malaria Institute of India, was to collect all relevant information concerning malaria in India, train personnel, and provide assistance and advice wherever required. It had undertaken research and initiated measures of control in almost all parts of India. Two other organizations working in India were the Ross Institute of Tropical Medicine, lately under the direction of Sir Malcolm Watson, and the Rockefeller Foundation, which had for some time carried on research and control, more especially in South India.

Specific Control Measures

In the last part of his paper Sir Rickard Christophers sketched some of the actual measures of control which have been carried out. In Bombay in 1908 it was found that malaria was being actively propagated in parts of the densely packed city by a particular species of anopheles, *A. stephensi*, which established itself in dark household wells in five-story-high Parsee tenements. A malaria survey was made, complete control established, and it soon became scarcely possible to find an unprotected well or cistern. Later the anopheles was found breeding in flooded cellars and in sheets of water on cement in large buildings under construction. Appropriate measures were again taken, and Bombay was now practically malaria-free.

Sir Rickard mentioned that he himself was sent to make an investigation into the prevalence of malaria among the convicts of Port Blair penal settlement in the Andamans, and discovered the role played by *A. ludlowi* (or *A. sundiacus*, as it was now called). The choice of more suitable sites in the healthy country away from shore and the filling in of local salt swamps made a great difference. He referred also to the Sarda canal scheme, a large-scale operation lasting some nine years and carried out in one of the most deadly hyperendemic tracts in India, in which every form of measure, direct and indirect, was used to combat the malaria menace. Other works in which malaria operations under competent malariologists were started from the earliest stages were the reclamation operations at Colaba to the south of Bombay and the construction of the new harbour and its railway at Vizagapatam.

New Delhi offered probably the first instance of the site of a projected capital being determined by a malaria survey. It was first proposed to build this modern city to the north of the existing Delhi, but overwhelming reasons on the basis of a malaria survey were found against this site, and the healthy site to the south was chosen. The speaker finally referred to the work carried out in the tea districts of Assam by the Ross Institute. Its most conspicuous feature had been the large-scale employment of new biological methods of control. One of the special methods was the use of shade plants of selected type to cover in the watercourses and so prevent the breeding of *A. minimus*, by far the most important carrier. Flushing by automatic apparatus was another much-used method.

Sir Rickard Christophers added that it was malaria research which had vitalized everything in connexion with control work, and to eliminate or subordinate research at this stage in order to confine attention to practical results would have a most damaging effect on progress.

Reports of Societies

MEDICO-LEGAL PITFALLS IN OBSTETRICAL AND GYNAECOLOGICAL PRACTICE

A joint meeting of the Medico-Legal Society and the Obstetrical and Gynaecological Section of the Royal Society of Medicine was held on February 19, Dame LOUISE MCILROY presiding, to discuss medico-legal pitfalls in obstetrical and gynaecological practice. Abortion was excluded from the discussion.

Negligence in the Operating Theatre

Judge W. G. EARENGEY, K.C., discussed the legal aspect of responsibility for instruments or swabs left in the body after operation. There was a dearth of reported cases on this subject in English courts. Conformity with the general practice of the profession did not compel a jury to find that there was no negligence; if it did, the profession would be setting up standards inconsistent with the general law, but evidence of general practice carried considerable weight. Nor was failure to conform with the usual methods necessarily evidence of negligence, otherwise the adoption of a new method would be fraught with grave risk for the surgeon. It would be difficult to persuade a jury that an instrument or swab could be left behind without negligence. Exceptional cases might occur, when the patient suddenly developed signs of collapse and in order to save his life must be sewn up before all precautions could be taken, but the burden of proving these facts strictly would rest upon the person alleging them. In James *v.* Dunlop[1] Lord Justice Greer was reported as stating that the duty resting on the theatre sister in this respect did not relieve the surgeon, and Lord Justice Scrutton laid it down that if a surgeon put swabs in a body it was his duty to take them out, and not merely to rely on the count of a skilled person. In Gold *v.* Essex C.C.[2] Lord Greene said that a nurse employed as the servant of a hospital did not cease to be such when placed under a surgeon's orders in the theatre; she was therefore not his servant, and he was not responsible as principal or employer for her negligence.

Special Problems in Obstetrics

Mr. EARDLEY HOLLAND said that there were probably more pitfalls in obstetrics and gynaecology than in any other branch of practice, this branch having so many important, intimate, and delicate implications in social life. He instanced the following problems:

1. Mistakes in diagnosis of pregnancy, especially when first disclosed in operating theatre.
2. Uncertainty about duration of pregnancy, including viability, prematurity, and post-maturity.
3. Definition of "live birth" and "dead birth" and signs thereof.
4. Surgical sterilization, including liability, if any, of the operator should pregnancy occur after operation for sterilization.
5. Consent to operations, especially those depriving a woman of child-bearing capacity.
6. Puerperal infections which could be said to have been favoured by absence of precautions on the part of doctor or hospital.
7. Artificial insemination between husband and wife and the precautions to be taken by the practitioner to safeguard himself and the child.
8. Evidence of virginity in nullity cases, and the deliberate destruction of the chief evidence of virginity by pre-marital hymenectomy (as a routine measure he considered this unjustifiable).

Gynaecological practitioners should keep the fullest clinical notes of all cases, all letters received, and copies of letters written, make a thorough examination of the patient, never take for granted the correctness of a diagnosis made by another doctor or gynaecologist, and never operate on a patient before personally interviewing and examining her. An eminent lawyer had said that more danger lay for the gynaecologist in what he said than in what he did. When a mistake was made and aspersions were cast, the practitioner should be always courteous, frank, tactful, and considerate, rather than take an attitude of righteous indignation and injured innocence; otherwise the tolerant patient might become the vindictive litigant. Some "pitfalls" were crafty devices to entrap the medical man. These generally concerned the termination of an unwanted pregnancy, and the young and unsuspecting gynaecologist was chosen as a victim. In very rare cases a doctor and patient might act in collusion. The doctor would send a request for the curetting of one of his patients for menorrhagia, or the patient might describe fictitious bleeding (he had even known a quantity of bullock's blood to be used to add colour to the deception). It was necessary to be on guard against the abortionist who started the business and left it to others to see it through.

Legal Position of Sterilization

Dr. LETITIA FAIRFIELD said that the legal position of sterilization was fully explored in the decade preceding the war, and had in no way been altered since. Therapeutic sterilization—that is, an operation considered necessary for the patient's life or health—was legal, and the only way in which the gynaecologist could render himself vulnerable was by neglecting to obtain a full and explicit written consent from the patient and, if possible, from her husband. Eugenic sterilization—not necessary for the patient's health, but intended to prevent the propagation of unhealthy offspring—was on more debatable ground. In theory at least the surgeon performing such an operation laid himself open to prosecution under the ancient law of mayhem or under the Offences against the Person Act. But as modern conceptions of the hereditary transmission of disease were unknown, and the operation on the female not contemplated, when those laws were formulated, and as no relevant case had yet been before the courts, it was impossible to say what view a jury would take. All authorities seemed to be agreed that the sterilization of mental defectives with or without their consent or their parents' consent would be illegal.

Another pitfall, that of artificial insemination, was much less familiar, and she thought it had never been discussed from the legal standpoint in this country. The birth of a child by artificial insemination between husband and wife would not deter an action for nullity, but might well render the case more difficult to establish. A very different position was created with the use of alien or donated semen, a practice apparently growing in the United States. Even in the most favourable instances the position of the offspring was rendered dubious, while the practice obviously lent itself to trickery, such as the defrauding of the heir presumptive to title or estates. Two schools of thought had arisen in the medical profession in America. One took the view that the gynaecologist's only aim was the parents' happiness, that he should advise them to sign no document, forget all about it, and be prepared to support the statement by robust perjury if necessary that the child was theirs. But the American Medical Association[3] discouraged this view, realizing that the status of the child might be challenged by interested parties; therefore it advocated very explicit consent documents and legal adoption of the child, though it might be doubted whether any of the precautions would really be of much assistance in establishing the child's status or defeating a conspiracy to defraud.

"Negligence" in Obstetrics

Mr. ALECK BOURNE said that the professional idea of negligence and the layman's idea were different. The medical man knew that failure to apply certain tests or treatment—for example, examination of urine at frequent intervals in late pregnancy—constituted actual neglect of necessary precautions, but the patient did not realize that she had been neglected if the urine was tested once or twice during the whole time of the pregnancy. On the other hand, a patient might regard herself as neglected, because no interference was made during the protracted first stage of labour and the child was born dead. Complete note-taking at every ante-natal visit was an important precaution against a later charge of negligence. But the most important of all obligations was that of being present at the actual delivery. If a doctor failed to be present the antecedent reassurance that everything was normal counted for little in the lay mind. One result of failure to be present where there was no automatic gas apparatus was that the woman would be deprived of an anaesthetic, and this occasionally suggested the idea that the doctor was callous and indifferent to suffering, a more serious reflection on his reputation than almost any other.

Preservation of Professional Confidence

Dr. ROBERT FORBES, secretary of the Medical Defence Union, said that there was no field in medicine where more intimate secrets were revealed than in obstetrics and gynaecology. If such matters were learned by practitioners under the seal of confidence, how came it that there should be any need to discuss the difficulties inherent in the preservation of professional secrecy? By whom and in what circumstances was it challenged? The immediate answer was that there were a number of occasions when the rule of professional confidence had to be adjusted to the realities of the moment. As an ideal the observance of confidence was excellent, but occasions arose when modification or adaptation was essential. He believed that the continued existence of the rule of confidence in so high a proportion of cases was due to the waiver of the rule when common sense and natural justice dictated a relaxation. If practitioners were to insist upon its observance upon every occasion no matter who suffered or whose interests were imperilled, it would not be long before the prerogative was lost.

In some further brief discussion Mr. GREEN-ARMYTAGE mentioned the "pitfall" of puerperal sepsis following contact infection in the maternity ward. Dr. WILLIAMS mentioned a hypothetical case in which a couple, having given up the hope of children of their own, consented to the operation of artificial insemination and a child was born. Three or four years later, the difficulty apparently having been overcome, another child was born, and the question arose as to which was the real heir. Judge EARENGEY said that in the case of letters patent for an earldom the heirs were said to be those "of the body," which apparently would rule out the first child. Dame LOUISE MCILROY, speaking on the issue of professional confidence, expressed the view that nothing except a case of very serious crime justified the practitioner divulging anything in court which had been revealed to him by the patient unless the patient gave consent.

Correspondence

Freedom to Practise

SIR,—In his admirable letter (Feb. 13, p. 200) Dr. E. U. MacWilliam writes: "We want, before every other professional consideration, freedom to function as doctors in response to the demands of our patients. . . ."

There must be thousands of practitioners who wish above all to keep that freedom, and hundreds of thousands of citizens who wish us to keep it, yet we and they remain almost silent. I believe this is because, bred up as we have been to freedom and knowing that we have used it worthily, we cannot believe that in this country it will be taken from us. Yet Sir William Beveridge puts at one short remove the question, "Is private practice worth preserving?"; and it is clear that as a direct result of his Social Security Plan it may indeed cease to exist.

The freedom to agree with a patient to be his doctor, to arrange to see him at our house or his bedside, to give him the time his case requires, to give our personal opinion, accepting full responsibility for our advice, to abide by that opinion and see the matter through, to choose, on occasion, the surgeon or consultant we judge to be best suited to his needs, to take our part in consultation and operation, and to remain throughout the man in charge, to have no obligation to disclose any part of our transactions with our patients to anyone, seems to many of us the very essence of good medical practice, and it is in private practice alone that this freedom exists in full degree. It is for this professional freedom that we renounce such lesser freedoms as the right to be off-duty in our own homes, and are content to be, as you have put it, the servants of our patients. It is the consciousness of this freedom in a regimented world that sustains our self-respect and supports us through laborious days and hours, and I am sure it is this same freedom which gives us the respect of so many of our fellow citizens. It is as free individuals, not as members of any organization, that we are consulted and trusted.

---

[3] *J. Amer med Ass.*, 1938, 1832

We and our patients know that we do, in general, serve them well. We know they do not choose us for the glossiness of our cars, but because they believe us to be good advisers. We know we are not reduced to antiquated futility by the absence of an electrocardiograph from our consulting room or by not being whole-time members of a clinical team. We know we are not deflected from honest practice by greed of gain. We know, in fact, that we are doing a good job, like our fathers before us, and we feel it right that we should be allowed to go on doing it, and our sons after us if they wish.

We are not unaware that circumstances limit these freedoms, sometimes severely, and we know they are sometimes abused. The obvious answer is to loosen the bonds of circumstance and to educate or discipline those who abuse their freedom; but to abolish the freedom, to make good independent practice permanently impossible, must seem to some of us an act of the same order of folly and destructiveness as to eliminate the family because some families are for ever quarrelling and some people are brotherless orphans.

Reformers tell us that many citizens have in fact only one doctor to choose from, that others do not exercise their right of choice, and that many doctors are fettered in their practice by poverty and other circumstances. They state or imply that we seek to defend a freedom which scarcely exists. No practitioner can offer statistical evidence on this point; he can only reply that he and his patients do, to his certain knowledge, fully exercise the freedom they at present enjoy; but in any case there is the world of difference between a freedom existing as a right, though stifled by economic circumstances or human inertia, and a freedom extinguished by legislation.

In a complete, whole-time medical service we should, of course, lose, *as a matter of right*, all the freedoms I have enumerated and many others as well. How many we should exercise under sufferance would depend upon our immediate or more remote superiors in the service, on the Minister in charge, and ultimately on Parliament and the electorate. No one with experience of State service can doubt that they would be substantially curtailed. But that is, perhaps, not the immediate prospect; it is, rather, an all-embracing "panel practice," and it may be argued that the "panel doctor" is still professionally free. He has, indeed, considerable theoretic freedom, though it hangs precariously on existing but mutable terms of service; his clinical notes are not his property, and he is conscious of the presence of a *tertium quid* in all his relations with his patients. But unless he is a philanthropist with a private fortune his power to give his insured patients really good service depends at present upon his having enough private patients to make it economically possible. Private practice, as matters stand, both sets the standard for good panel practice and actually pays for it.

Our private patients are not always good judges of doctors or doctoring, and they sometimes default, but this can be said for them: in general they demand from us the best we can give; by and large they reward us according to what we do or try to do for them; when they have the means they are ready to pay fees which make it possible to do good work, and they very often add their thanks. So far the State as an employer of practitioners does none of these things, and it shows no sign of repentance or intention to reform. Its only standard of excellence is that which produces no complaint; it gives no reward for good work; and it has consistently paid the smallest capitation fee for which the practitioner could be induced to work at all. It never thanks or honours us in any way.

Failing a revolution, spontaneous or enforced by a united profession, in the attitude of the State to general practice, is it not certain that we are heading for a service free for all but of a hopeless mediocrity, a service in which the daily flood of trivialities and the inadequate and grudging pay will stifle good work, repel good men, and drive the unsatisfied patient into the arms of the unqualified practitioner waiting outside? Something perhaps not very common but very good, one of the best manifestations of the art of medicine, one of the most satisfactory of human relationships yet devised, will have been lost to this country, which has especially cherished it; and if the family doctor is indeed, as he is so often called, "the backbone of the profession," then the profession will have caries of the spine.—I am, etc.,

Hampstead LINDSEY W. BATTEN.

Future of Women in Medicine

SIR,—There has been much recent discussion about post-war planning of medical education and the future of women in the profession of medicine. I believe that this subject needs an entirely fresh outlook. A debased "feminism" is still all too prevalent among women, and is very much in evidence in the medical profession. There is no need for women to pine after men's prerogatives, privileges, and honours. There is no need to clamour for admission to men's hospitals; to be greedily insistent on their "rights" to have the same training, to attend the same hospitals, to hold the same appointments, and to enjoy the same privileges as those open and available for men.

In reaching for the deceptively bright shadow, these ardent, and at times militant, enthusiasts miss the substance. Women are created women; men are created men. Each has its own abilities, possibilities, and obligations. In this age of ours the essential dignity and worth of a womanly woman in her own right and in her own sphere are being forgotten, and forgotten, unhappily, very often by women themselves. This dignity is violated when a woman tries to occupy the sphere which essentially belongs to a man, just as a man's dignity is violated when he tries to occupy the sphere of a woman. Woman was created for the dignity, nobility, and responsibility of wifehood and motherhood. If circumstances or character and vocation demand that a woman should follow some profession or "gainful occupation" before, instead of, or after, marriage, then to maintain the dignity and nobility of womanhood that profession or "gainful occupation" must remain still within a woman's sphere. This principle should be widely recognized in schools, universities, training centres, and employment bureaux.

I maintain that through neglect of these principles the average medical woman to-day is not pulling her full weight in the profession or in the community. Large numbers of the women qualified to-day—and I must count myself among them—have neither the character nor the vocation necessary, and should never have been encouraged by their parents and teachers to "take up" medicine nor permitted to continue to study it. Further, the training that they received was, and is, in many ways unsuitable for medical women.

It is with these thoughts urgently present in my mind that I beg the courtesy of your pages for this letter and the appended suggestions for the reform of medical women's education, knowing that only through your *Journal* will they reach the wide medical public and have the free discussion which the gravity of the subject demands. Finally, I would say that the remarks I make below about the training of medical women in social responsibility could well be applied to the training of medical men. If this had been so in the past we should not now be witnessing the deplorable cynicism and *laisser faire* which enable your *Journal* to publish letters like that by Dr. Lilias M. Blackett Jefferies (Dec. 12, p. 714) and by Dr. Marie Stopes (Jan. 2, p. 30) deploring the wide use of certain contraceptives because, forsooth, of their unreliability. Nor should we have beheld in the years between the two wars the acceptance of the principle of birth control by many local medical officers of health and borough councils and even by the Ministry of Health, nor the widespread acceptance of this principle by medical men and women to-day. This state of affairs is very largely responsible for a terrible and frightening prospect for our nation. In 30 short years—within the lifetime of many of us—we shall see the old age pensioners outnumbering the children in this country, and in 100 years the prospect of the complete extinction of our race (Beveridge Report, pp. 91 and 154).

I suggest the following changes in the education of medical women.

1. Co-education is fundamentally dangerous, especially in a medical school, for the following reasons: (*a*) impairment of concentration and work due to proximity of the sexes; (*b*) lowering of standards, first of modesty and then of morality. These evils can only be avoided in a community with deeply held Christian moral principles. This is unhappily not the rule to-day. Hospitals and medical schools for the training of women should be entirely separate from those for the training of men, both for the reasons given above and because the medical training of men and women should emphasize different aspects of medicine. "Quality not quantity" should be the aim of those in charge of the medical schools for women. To that end, therefore:

2. Let the entrance age for students be raised to 22 years; this will eliminate all, probably, but the best.

3. Let a condition of entrance be three years' training as a nurse in a general hospital. This will not only be a training valuable in itself, but ensure fixity of purpose and confer a mental discipline which is, believe me, highly necessary.

4. Let the aim of the teaching staff be to train medical women, not to teach women to try to be medical men.

5. Let it be accepted that women should administer to women and children only. In the hospitals to which the medical schools are attached male patients should not be admitted, even to the casualty department.

6. The hospitals should be staffed entirely by women. With the cream of women in the medical schools, never fear but that women of the quality of Dr. Garrett Anderson will come again to rule these hospitals.

7. Let the house staff be chosen on the basis of 75% by special house staff examination and 25% by character and qualities obviously useful to the hospital's future.

8. At the schools of medicine and at the hospitals special attention and training should be given to develop a sense of social and public responsibility, and to this end sensible experts, not necessarily medical, should be co-opted to the teaching staff, of the calibre, for example, of Dr. R. D. Lawrence's dietetic Sister. There will then be built up among medical women a tradition of leadership and special excellence in all matters important to the welfare of women, girls, and children.

9. There should be no birth control clinic at the hospitals. A birth control clinic ill becomes any hospital. Contraceptives ought to be especially abhorrent to women. It is more than pitiable that it should be a woman who confesses herself "proud" to have opened the first birth control clinic in this country. Marshal Pétain's plaint, "France has too few sons," might well be ours for England. Medical women should feel this deeply. It is their place and should be their mission to see that there are no more high priestesses of this woeful practice.

10. The qualifying regulations for women should be altered to fit in with these reforms.

Now is the time for every medical woman to think and to take stock of her position in the profession of medicine. Medicine is not for any and every woman; it is for the inspired, the gifted, the special few. This must be realized in choosing the future entrants to a school of medicine for women and in the training of these entrants. Also I cannot emphasize too strongly that medical men must be medical men, and medical women must be medical women, each with its own functions and responsibilities, working together for the common good. Then and only then will the medical woman pull her full weight in the profession and in the community, remembering and being proud of her sex and her special sphere.—I am, etc.,

Stoke Ferry JANE SCOTT CALDER.

The B.M.A. and the Beveridge Report

SIR,—The difference in wording of the two motions shortly to be placed before the Special Representative Meeting of the B.M.A. and the Special Conference of Representatives of Local Medical and Panel Committees may have some other significance than that the one reads even more placatory than the other. There is evidence of increasing resentment among doctors serving in the Forces at the increasing probability of the abandonment of their ancient privileges as practitioners of medicine in favour of new principles which they themselves have had no opportunity of debating, and which are, for their establishment, conditional upon the magnitude of their personal sacrifices. It is worth recalling, too, that the Minister of Health deprived us of the right to elect members of Local Medical and Panel Committees. These signal facts are a challenge to the right and competence of the special conference to meet and adopt a motion when no mandate has been conferred.

Debatable points of policy and principle are matters different from pseudo-collective attempts to secure any betterment of pre-existing terms and conditions of service. Local Medical and Panel Committees, through their representatives on the Insurance Acts Committee, have failed to achieve a reasonably expected increase in the capitation fee. Very recent political events, however, convince me that the fundamental point at issue is not that panel practitioners must continue to be underpaid, but whether or not there is any representative body with either the power or the ability to negotiate on their behalf. Even the chairman of the I.A.C. has given expression to a feeling of having been "browned off" in suggesting that the whole body of the profession should support the claim of the panel practitioner.

There is a mort of difference between wishful thinking and unthinking wishing. The one is ambitious, the other defeatist. The profession, upon the adoption of the motion I criticize, will succumb in the fight between democracy and the new bureaucracy. Action, if any be needed, must be taken now in no uncertain measure. No faith will be broken if the motion should read: "The profession will oppose any scheme for comprehensive health services unless the character, terms, and conditions of service are predetermined in agreement with the medical profession."—I am, etc.,

MAURICE E. WIGFIELD.

SIR,—There seems to be an impression that the Beveridge report has caught the B.M.A. unprepared: on the contrary, we are very well prepared indeed. The Medical Planning Commission has received the views of all the important bodies and has got very considerable agreement on the broad principles. In addition the discussions in study groups, panel committees, and so on have been of great value.

It is true that the profession has no detailed scheme to offer, but that is not our business. So far everything has worked out most opportunely. The principles are agreed by most of us, and the same principles appear to have the support of the Government (see Sir John Anderson's speech). The Minister of Health is a Liberal, who may be expected to sympathize with the statement put out by his party, which was so acceptable to the profession. And finally the whole matter is to be discussed in a calm atmosphere and is not to be made a party business at a general election.

Great credit is therefore due to the B.M.A., except that I think the hurried calling of meetings all over the country to attempt to persuade us to go back on our decision that the well-to-do should be excluded from the scheme is a most foolish and undignified move. It is always a mistake to give away bargaining counters in advance, and I hope it is not too late to repair this mistake.—I am, etc.,

Hendon, N.W.4. R. W. COCKSHUT

SIR,—The resolution to be moved at the Representative Meeting of the B.M.A. on March 31 accepts the principle of a comprehensive health service available to all members of the community, with the proviso that people who wish to should be able to obtain medical services from doctors within the scheme by private payment.

At the present time there is a national food service designed to give a fair distribution of essential foods to all members of the community. Those who buy and sell outside the scheme are called "black marketeers," and are open to universal contempt and to legal penalties. Surely, proviso (*b*), in demanding private practice outside a *comprehensive* service, is no more than a demand for an officially recognized "black market." It will be tragic if such a demand receives the approval of a Representative Meeting of the B.M.A.—I am, etc.,

London, N.11. C. M. FLETCHER.

SIR,—While welcoming the recommendation of the Council of the B.M.A. advising co-operation with the Beveridge scheme, I think the provisos they make call for further discussion.

First, it seems surprising that the medical profession should consider whether or not they will co-operate in such a scheme. We repeatedly and rightly state that our first consideration is service to the patient. Since we live in a democracy, Parliament represents both doctors and patients. If, therefore, Parliament decides that the comprehensive medical service should be adopted, it means that the majority of patients or potential patients are in favour of it. There is, I think, no question whether we should, to serve the patient, oppose the scheme. They have asked for it. We can only demand, and justly so, that we be consulted about the organization as it affects our ability to carry out this service in the most efficient manner.

Secondly, the recommendation states that only if the Beveridge scheme is accepted as a whole can we co-operate in putting it into action. Your leading article (Feb. 13, p. 193) rightly points out that the attack on want and idleness is "a public health measure of the first importance," and doubtless any comprehensive medical service would be far more effective if backed by these other plans for social security. But the expected has happened, and the Government has not accepted the report as a whole. We are surely not going to refuse to take at any rate one step towards a better medical service, although all the public health measures are not as ideal as we could have wished.

Thirdly, for what reasons do we make the proviso about private practice? The only conclusions as I see them are these: (1) We think it will increase efficiency. As one member of the Council put it, State-provided service and private practice would act as a spur to one another. But attention to private patients can only detract from the time and consequently the efficiency which can be given to insured patients, will divide the allegiance of the doctor, and tempt him to give better service to the paying patient. If private practice is spurred on, then insurance practice is forced back. (2) We intend to give better service to paying patients. This has been dealt with by correspondents and leads to the assumption that the new medical service is handing out second-rate treatment. (3) We want to make more money. If this is the case, it is never stated in the discussions. We have every right to demand adequate pay, but do we demand private practice to increase our incomes? If this is so, then it is a poor opponent to put up against those who are striving for the best medical service that can be devised at the present time.—I am, etc.,

Oxford. A. DELISLE BURNS.

SIR,—There is one aspect of the proposed extension of complete medical services to all and sundry which I have not seen mentioned in any of the letters in the *Journal*. The question is, If the whole population is to be more or less "on the panel," how will the present number of doctors be able to attend them? As once a patient, previously private, becomes a "panel" patient his attendances increase greatly.

The general practitioner for years has been overworked with very little time for leisure, and if medical attention is to be popularized by being made available at little cost there will be no limit to the exploitation of the medical profession. What safeguards are we to have against this? I hope our negotiators will bear this very important point in mind. Would any lawyer contract to do all legal work necessary for a client for 9s. 9d. a year if litigation was as common as minor ailments are?

Most general practitioners will agree that panel work is extremely exhausting; that is probably why local B.M.A. meetings are poorly attended: exhaustion of the doctor is the real reason, not apathy, as has been stated. I agree with Dr. A. E. Moore (*Supplement*, Feb. 20, p. 27) that only by a questionary addressed to each individual practitioner can the real wishes of the profession be arrived at. Our negotiators should be instructed to make it quite clear that consideration must be given to the health and welfare of the doctors who are to run the scheme, and that conditions which cause gross overwork such as have been prevalent for many years will not be tolerated.—I am, etc.,

Blackburn. F. E. EDWARDS.

Venereal Diseases

SIR,—In the war against this scourge the Archbishop of Canterbury deplores that only the medical point of view is taken into consideration and that the religious aspect is not in evidence. When we look into the past, how the Church condemned unfortunates who through misfortune and ignorance became victims, is it any wonder that the meddling and self-righteous divines should have been ignored?

In the past 50 years, the time I have been in active practice in many parts of the world among many peoples, I have been disgusted by the utter lack of sympathy of the clergy of the Church, who have done their best not only to wrap themselves up in ignorance and intolerance of the difficulties of life but actively to prevent members of their Church from intelligent inquiry. When the late Lord Roberts over 40 years ago took some active precautions to mitigate disease in India the princes of the Church condemned him as harbouring vice, and demanded withdrawal. When a colleague of mine wrote a strongly worded article about the same time advocating precautions, his appeal was turned down, mainly on religious grounds. Fortunately, science, education, and reason have gone ahead, and people are not influenced by religious and superstitious threats, and divines have had to identify themselves with public opinion as they have had to water down and modify their assertions on religious belief generally.

This is an entirely medical matter and should be treated in a reasonable and common-sense way. Education has been lacking in this direction, and information on the most important human function we possess, its object and control, and in the matter of keeping sexually fit has been mainly obtained through secretive and "smutty" channels. Let us hope that light is at last coming through the darkness, stupidity, and prudery of the past, and that this terrible scourge will be recognized as an ordinary disease. Only on such sensible lines can we hope for success.—I am, etc.,

Southbourne. E. A. CHARTRES.

Scientific Freedom and Social Medicine

SIR,—Dr. Geoffrey Bourne (Feb. 20, p. 227) has vigorously attacked a problem which badly needs ventilation. It is of the utmost importance that in our medical planning we safeguard the professional independence of the experienced clinician, and allow him an effective voice in the direction of the machine of which he is a part. Salaried medical men are usually too frightened of what might be the personal consequences to say what they feel on this subject. This is itself a serious criticism of the bureaucratic system, but probably an unjustified one. No sensible administrator regards the system under which he works as sacrosanct or will resent views expressed in good faith.—I am, etc.,

ELIOT SLATER.

Treatment of Cerebral Contusion

SIR,—Surg. Capt. Lambert Rogers (Feb. 6, p. 151) persuasively attempts to counter prevailing scepticism (to which the writer has long subscribed: *Brain*, 1932, **55**, 549) regarding the importance of cerebral oedema as a complication of cerebral contusion. There are, indeed, few head centres in this country which approve of the treatment he advises.

With regard to the clinical argument that his cases do better, it should be pointed out that to prove this he should inaugurate an accurate follow-up investigation on lines comparable to those described by Symonds and Russell (*Lancet*, 1943, **1**, 7) and Guttmann (*British Medical Journal*, 1943, **1**, 94).—I am, etc.,

W. RITCHIE RUSSELL,
Major, R.A.M.C.

Haemoglobinometry and Use of the Haematocrit

SIR,—We are glad to read the report to the Traumatic Shock Committee of the M.R.C. (Feb. 20, p. 209) and to note that serious attention is at long last being given in this country to the question of haemoglobin determinations. But the proposal to estimate the Hb concentration from a determination of the cellular iron is certain to lead to confusion. It has been shown by Barkan and confirmed by various workers, including ourselves, that the erythrocytes contain iron which is not in the form of Hb, and we have shown that the proportion of non-Hb cellular iron rises from 7% normal to as much as 40% of the whole in some anaemias.

In such circumstances we think it futile to remove the plasma before determining the total cellular iron. The plasma iron is negligible as an influence on the cellular total, and should be amply sufficient for general purposes to remove the supernatant plasma after centrifugalizing. The plasma remaining in the packed cells was demonstrated by one of us (C. E. J., 1932) to be about 10%, which would influence the total iron by about 1 part in 1,500. It is true that the committee emphasizes that the proposal is only an interim one, but interim methods have a habit of sticking. We consider that gas analysis with the van Slyke apparatus is far the best method of calibration.

We fail to understand the committee's opinion that a knowledge of the Hb of normal men would be desirable. Such information is already available. Many determinations by gas analysis have been done all over the world, and there is fairly good agreement that the male normal is about 15.5 to 16.0 g. %; in this country the only work published is by Jenkins and Don (1933). It was one of the largest gas analysis determinations ever undertaken in any country, and its results agreed with the rest of the world.

The technical difficulties inherent in photometric methods are well known, but most of them require nothing more than a little common sense. But the difficulty of a permanent standard is serious, and for that reason we think that the flicker Hb-meter, using the Simmance-Abady head (C. E. J., 1930), has much to recommend it. Our experience of it agrees with Stokes's statement that there is better agreement between different observers using a flicker photometer than with any other form of visual photometer.

The committee deserves every encouragement in work which may end 20 years' stagnation, and we will conclude by recording our own opinion as to the ideal method of measurement. We believe that the only satisfactory instrument is the spectrophotometer. It is essentially superior to every form of colorimeter, including the Pulfrich type; there is no trouble with standards—once calibrated its permanency is absolute: its standards are no more than a wave-length and an extinction coefficient. Its cost is very great, but we firmly believe that sooner or later it is bound to be the standard instrument of every laboratory.—We are, etc.,

C. E. JENKINS.
Manchester. M. L. THOMSON.

A Member Resigns

SIR,—I think a considerable amount of the feeling of stultification experienced by members of the B.M.A. is due to two facts. (1) The Council exercises an arbitrary choice as to which resolutions shall be debated at the Annual Representative Meeting. This difficulty could be met either by choosing certain resolutions from each subject by lot or by allowing the A.R.M. to elect three of its members to choose which resolutions shall be debated. (2) We feel that there are a large number of members on the Council who have been there for years, who are automatically re-elected every time, and who are completely out of touch with the feelings of their members. It would be a wholesome reform if any member of the Council who had been on it for 3 years should be ineligible for re-election when his term expired. He would become eligible again one election later.—I am, etc.,

Colchester. M. E. LAMPARD.

*** Many letters on this subject have been received, but limitations of space make it necessary to discontinue this correspondence.—ED., *B.M.J.*

Mitral Systolic Murmurs

SIR,—Dr. William Evans, in his article on mitral systolic murmurs (Jan. 2, p. 8), has certainly put the cat among the pigeons. At first I thought that, after nearly forty years of continuous auscultation of hearts and trying to estimate the significance of abnormal noises, especially while on medical boards, the complete fogging induced in my mind by his article was the result of my own senility, though I was not conscious of any mental deterioration. But now that Dr. C. H. Ross Carmichael (Feb. 6, p. 172) "and several colleagues" also find themselves a little confused I feel happier.

All noises or sounds must be the result of some physical phenomenon: nobody at least can dispute that; and I feel that I am now old enough to demand from the cardiologists something a great deal more definite than I am getting. I do not like to be put off by being told that such-and-such a murmur is "irrelevant" or "innocent" and that its cause does not matter. Again, Dr. Evans states in two consecutive paragraphs in juxtaposition that "when the murmur is decidedly louder in the upright posture it is the innocent kind"; and then, "when a systolic mitral murmur becomes louder in the reclining posture the innocent nature of the murmur can be presumed." In other words, whether it is louder sitting up or lying down it is "innocent." Frankly, that does not make sense to me. By "mitral systolic murmurs" I should understand murmurs heard at the mitral area and caused by lesions of, or in the vicinity of, the mitral valve; so why drag in aortic stenosis and incompetence?

Because, in necropsies, Dr. Evans does not always find enlargement of the left auricle, he forbids us to use the term "mitral incompetence," thereby implying that there is no such thing *per se*, and without mitral stenosis. But a little further down the paragraph he says: "This sign [auricular enlargement] is absent unless some cause other than mitral incompetence is operating," thereby tacitly admitting that mitral incompetence does occur *per se*. Lastly, and to get down to brass tacks, how can a loud or soft organic systolic murmur (granted that it comes under my definite heading of "mitral murmurs") impinging directly on or incorporated with the first sound heard at the mitral area be caused by mitral stenosis? Surely, stenosis or no stenosis, there must be regurgitation of blood back through the mitral orifice. What else could cause the sound we hear? The blood is already in the ventricle before we hear it, the ventricle contracts, and unless the sound is caused by regurgitation back through the valve it must be caused by something else, and is therefore not a mitral murmur. If it *is* caused by back-rush through a damaged valve, then the valve is incompetent; therefore there must be such a thing as "mitral incompetence." You cannot have it both ways.—I am, etc.,

Stowmarket H. S. GASKELL.

Periodicity of Relapses in Tuberculosis

SIR,—Your reviewer's quotation (Feb. 27, p. 255) from Dr. J. Burns Amberson on the need for promptness in the treatment of new tuberculous lesions if we "wish to accomplish maximum results at the most opportune time" reaffirms a main principle of value in the treatment of most diseases, but one often forgotten, and rarely applied as energetically as possible. Sometimes it can abort attacks, from respiratory catarrhs to cancer recurrences. As applied to relapse cases of tuberculosis its use would be greatly facilitated if there were any means of telling beforehand when any individual patient was in danger of a relapse (as by various methods of blood examination). Relapses have followed influenzal attacks often, but they may also have an intrinsic rhythm.

My recent study of over sixty cases of tuberculosis suggests that there is a cycle of activity in tuberculosis similar to that of the influenza-cancer cycle (Brownlee, 1919-23; Webster, 1938-42). Should this be confirmed by further research, follow-up methods would be facilitated (as, for example, the repeat examinations advised for mass radiography), and the principle of prompt treatment to new signs could be adopted more widely and more accurately.

Most of my personal observations have been in patients with tuberculous glands in the neck (*x*-ray and radium treatments), but a search in hospital reports and in the literature has shown a similar cycle in most types and sites. For example, an acute lung case (T. W., male, aged 36) showed four half-periods: onset 1914, July; worse in November; again in March, 1915; and July; and died in November (Powell and Hartley, *Diseases of Lungs and Pleurae*, 6th ed., 1921, p. 481). A more resistant case to begin with (Mrs. X, aged 29) showed a relapse after influenza at six periods, further exacerbation at one period, and death at the half-period (p. 484). Further studies are in progress. This preliminary note may stimulate others to search their records of relapse patients.—I am, etc.,

London, W.1. J. H. DOUGLAS WEBSTER.

Diphtheria and Diphtheria Carriers

SIR,—Few medical officers of health, one imagines, will fail to agree with the context of the letter by Dr. F. Lawrence Smith (Feb. 6, p. 171), nor with what appear to be his three most important contentions—namely: (1) That as a result of the progress of the national immunization campaign it "is not uncommon" to encounter "throats" where a "positive K.L.B. swab was a coincidence of no pathological importance." (2) That "it is imperative that medical officers of health should carefully investigate every case which is notified as diphtheria." (3) That in the absence of the precautions as indicated in (2), together with a deletion from the medical officer's register of such cases as were found to have been diagnosed on a positive swab but where the "diagnosis was completely at variance with the clinical evidence," the "Registrar-General's returns will continue more and more to give an erroneous impression of the influence, or lack of it, of immunization on diphtheria the disease."

Dr. Lawrence Smith's suggestion that the M.O.H. should on full investigation review and, if necessary, delete from his register notifications of diphtheria which he is satisfied are really diphtheria carriers is probably the best and most obvious in such districts where the M.O.H. has control of the isolation hospital or hospitals; but many of us whose areas are served by joint hospital boards have no such control. In our cases deletion presumably would follow only upon an agreement between the M.O.H. and the M.O. i/c hospital. In the absence of accepted definitions of "clinical diphtheria" and "diphtheria carrier" it is perhaps not surprising that there should be difficulty in arriving at this agreement.

Let me quote two definitions which do not appear to be very helpful: (*a*) In the Infectious Diseases Regulations (Scotland) a carrier is defined as one who has within himself the germs or other infective virus of an infectious disease, but has no other sign or symptom thereof, and who is certified by the medical officer of health and one other medical practitioner to be a danger to others. (*b*) Ker's *Manual of Fevers* (4th edition, p. 249) under "Types of Faucial Diphtheria" includes: "Those slight throat inflammations which are associated with, and probably due to, the diphtheria bacillus, but which do not present characteristic membrane and can hardly be regarded as clinical diphtheria. Some, indeed, may be merely instances of simple sore throat affecting a 'carrier' of the bacillus."

I suggest that the increased confusion visualized by my colleague can best be avoided by a policy which will be acceptable to the general practitioner, the M.O.H., and the M.O. i/c isolation hospital, and that such a plan should be encouraged by the Ministry of Health by a suggestion or order to the effect that: (1) Practitioners should be encouraged to swab all suspicious throats and to send to hospital all positive K.L.B. carriers. (2) Practitioners should be paid a fee for notification of carriers. (3) Isolation hospitals should undertake a Schick test of atoxic K.L.B.-positive cases as soon as the case is admitted. A Schick-negative result would warrant the elimination of diphtheria diagnosis. (4) Isolation hospitals should ensure the taking of a virulence test of the K.L.B.s. (5) The M.O.H. would be warranted in deleting a diphtheria notification upon evidence deduced from the results of (3) and/or (4), which results should invariably be transmitted to him by the isolation hospital.—I am, etc.,

H. G. DONALD,
Medical Officer of Health.

Bishop Auckland

War Neuroses

SIR,—I am greatly indebted to you and to Dr. W. Ronald D. Fairbairn for his article "The Nature and Significance of War Neuroses" (Feb. 13, p. 183). That I criticize details does not mean that I am not a whole-hearted supporter of his general thesis.

I cannot find myself in agreement with those who say that "so far as symptomatology is concerned the war neuroses possess no distinctive features differentiating them sharply from the various psychoneurotic and psychotic states which prevail in times of peace." My observation has been that it is precisely in symptomatology that *some* of the neuroses of war do differ from those of peace. I agree that the essential emotional structure is similar in neuroses of war and peace as also in normal and neurotic soldiers or civilians. But as I pointed out in an article you were good enough to publish in the winter of 1939, the circumstances of war, being emotional stimuli of unwonted intensity and suddenness, cause a symptomatology more florid, more extreme, and more essentially abnormal than do the more moderate and more slowly acting circumstances of peacetime life. This difference in degree of symptoms only really becomes obvious when weighed, in each case, against the personality of the patient before breakdown. Thus, in wartime a class of neurosis can be recognized in which the person was previously of good personality and quite without neurotic illness or even (discoverable) neurotic predisposition. These men and women under sufficient strain will break down, and often the symptoms then produced will be of this florid type. It is as though, in wartime, the ratio of "symptoms : personality," instead of being an inverse proportion, becomes at times a direct proportion: the better the personality the greater the symptoms (also the greater the stress required to cause them), whereas in peace it is more often the poorer the personality the greater the symptoms.

A young guardsman in the last war became a sergeant and received the D.C.M. and M.M. before he was 21. A near shell-burst during a severe bombardment rendered him unconscious. He regained consciousness in hospital in London. No physical injury being found, he was regarded as a case of "shell shock." He was invalided and has remained an invalid, a hopeless chronic hysteric. He had an exacerbation of symptoms in September, 1939. An editor of an important news service with an excellent record of health and personality became deluded and paranoid the day before the declaration of war in 1939, as a result of the stress of watching its approach. The whole content of his delusions was intrigue behind the scenes leading to war. A medical man of considerable achievement and good personality, and in a very responsible position, became a case of obsessional neurosis and in a highly aggravated state of obsessional doubt within a few weeks of the outbreak of war

In the last two cases removal from work and sympathetic and understanding management, without specific treatment, restored health and ability to work in two or three weeks. The doctor was able to carry out a similar responsible job throughout the bombing of London Of the editor I have not been able to hear, but I fancy he did equally well. Such violent breakdown and such easy cure are practically unknown in peacetime and depend upon the quality of the personality of the individual and the degree of the stress.

To understand neurosis, therefore, in war as in peace, is to understand personality. To do this one must realize that many of the phenomena we refer to as psychopathological are really psychobiological. By that I mean that the process which, in the upgrowing of a child, leads to the development of a healthy independent adult leaves a trail of emotional events and conflicts overcome, to the more difficult of which there may be a regressive return in times of great stress. Nor can regression itself be considered simply as a pathological mechanism. Two of my cases regressed, certainly, but when the significance of this regression was recognized and appropriate help given they were able to return to full adulthood. Had they not been quickly relieved of stress they might well have gone the way of the first case. The regressions that are thus a signal of distress should be recognized by doctors so that the personality may be saved. We must not be afraid of dependence It is sometimes, in adult life, useful as it was in childhood; but, as in childhood, it must be followed by a phase of wise weaning. The conflict, "infantile dependence" versus "adventuring into adult life," is present in all of us, normal and neurotic. Neurosis is merely a quantitative variation, at most a modification, and not a contradiction, of the normal.

With these and one or two other minor adjustments, one can accept the main thesis of Dr. Fairbairn's account of the nature of war neurosis. It is, after all, as he says, a psychopathology which is applicable to peacetime neurosis no less than to the neurosis of war. That these general ideas were the guiding principles of a large number of workers in this field before the war does not, however, appear from Dr. Fairbairn's article. The names of the Sutties—the late Dr. Ian Suttie and Dr. Jane Suttie—are particularly linked with the development of psychopathological ideas along this line; and those who are interested by the excellent article may like to read further in Dr. Ian Suttie's book, *The Origins of Love and Hate.*

—I am, etc.,

Cardiff. GEORGE PEGGE

"Calorie Control" Diabetic Diet

SIR,—Dr. R. D. Lawrence (Feb. 20, p. 234) thinks the basal principle of my diet untrue and dangerous and considers it as no argument for the new diet to claim that 528 patients have done well on it. Against such *ex cathedra* declarations argument is unavailing. The test of the "calorie control" diet is its usefulness in the control of diabetes. In my hands it has proved highly useful, and I hope that it may also prove useful in the hands of others.

Several questions have been asked about the treatment of in-patients. The following report is of one of the eight in-patients discussed in my article.

A girl aged 18 has been in the hospital repeatedly in diabetic or hypoglycaemic coma. On one occasion when she was admitted in ketosis her abdomen was opened on account of severe abdominal pain and a swelling which was thought to be a subphrenic abscess. A greatly enlarged liver was found and the abdomen was closed. The swelling disappeared after she had been stabilized. Subsequently she was admitted to Oldchurch Hospital in ketosis on Dec. 6, 1941. It was impossible to stabilize her on a normal fixed diet (No. 1 below) with protamine-zinc-insulin, and she was finally given 36 units of soluble insulin three times a day. She had a slight reaction at midday on the day before the following experiment was carried out:

She was given the following diets alternately:

Diet 1.	Carbohydrate 220 g.	Protein 68 g.	Fat 57 g.
Diet 2.	„ 389 g.	„ 26 g.	„ 6 g.
Diet 3.	„ 138 g.	„ 102 g.	„ 84 g.

The food was fairly evenly distributed between four meals at 8 a.m., 12 p.m., 3.30 p.m., and 6.30 p.m.

The blood sugar estimated at 2-hourly intervals was as follows:

Diet	1	2	3	2	3	1
7.30 a m ..	4	125	.21	31	.29	15
9 a.m	36	44	31	.21	25	31
11 a m .	18	11	24	08	105	.12

This girl had no reactions during the experiment, but she is one of the most unstable diabetics I have met Since discharge she has been on a "calorie control" diet. She has attended the clinic regularly and has not had to be readmitted, because she has been comparatively stable ever since.

This and the seven other in-patients discussed in my paper convinced me that all types of diabetes requiring insulin could be controlled on the new diet. Since then more than 200 in-patients have been treated on weighed "calorie control" diets. —I am, etc.,

London, E 1 A. C. CROOKE.

Anaesthesia for Laryngofissure

SIR,—I am in some agreement with Mr. Lionel Colledge (Feb. 20, p. 230) in his criticism of Dr. C. B. Lewis's method of anaesthesia with regard to the use of morphine and of the inflatable laryngeal cuff, as the first is apt to be dangerous and the second unnecessary. I am, however, in total disagreement with him when he claims that temporary tracheotomy is necessary, and that the operation under intratracheal anaesthesia is a perilous procedure. I yield to none in my admiration for the late Sir StClair Thomson and the pioneer work that he did for laryngology in general and for this operation in particular. His method, however, was certainly perfected before the days of modern anaesthesia.

I myself have not employed a temporary tracheotomy for the past twelve years. I find that intratracheal anaesthesia gives a smooth and even anaesthesia free from anxiety, and the tube lying in the interarytenoid fold is not in the way of the operation. As the growth is almost invariably situated in the anterior part of the larynx (it would scarcely be suitable for laryngofissure if it were not so), it does not really require any unusual dexterity to slip the catheter, at the moment of inspiration, along the posterior commissure. After the larynx is opened, the trachea is packed off with gauze so that no blood or secretion can possibly enter it. A suction tube may be useful but is not essential. At the end of the operation, after the larynx is closed, the catheter is withdrawn and the patient breathes comfortably *per vias naturales*.

Mr. Colledge is, I think, in some slight error with regard to Hahn's tube. This was never meant to be used in the larynx. It was designed for the trachea, and the inflatable part when blown up was supposed to prevent blood passing it. It was abandoned when it was found that gauze packing inserted into the trachea from the larynx was more effective. I might add that the leading American laryngeal surgeons gave up the use of a temporary tracheotomy many years ago.—I am, etc.,

London, W 1. WALTER HOWARTH.

The Outbreak of Small-pox in Glasgow

SIR,—I beg to refer to the article by Dr. C. Killick Millard on the outbreak of small-pox in Glasgow (March 6, p. 288), in which he criticizes me for adopting an immediate policy of mass vaccination instead of putting my faith in the vaccination of contacts of cases as they occurred and otherwise trusting to luck. This criticism has received considerable prominence in the local press here.

Glasgow has had bitter experiences of severe and lingering epidemics of small-pox. Dr. Killick Millard quotes the considerable outbreak in 1903 which occurred in Leicester. At that time small-pox was occurring in Scotland, mainly in Glasgow, in successive waves of considerable dimensions from 1900 to 1904; again in 1920 an outbreak of small-pox involving over 500 cases lasted from February till November.

I know of no other way of dealing with small-pox abroad in the community except by adopting a policy of widespread vaccination at the very outset. When small-pox makes its appearance, what is the problem facing the medical officer of health? His first duty is to secure the vaccination of all possible contacts. This was done in Glasgow as a routine on an intensive scale, involving the inhabitants living near the patients over a wide area, children at the schools where child patients had been attending, work places where adults had been employed, and all other possible contacts—all with the object of placing a wide cordon of protected persons round each focus of infection. The second duty of a medical officer of health is to ask himself whether these measures are likely to be sufficient. In the case of the Glasgow outbreak I came to the conclusion that the additional precaution of mass vaccination was necessary for three main reasons: (1) The first cases in the city were widely scattered and unrelated; (2) I have a wholesome respect for the capacity of small-pox to strike at a distance; (3) it would have been wrong to postpone general vaccination until small-pox had obtained a firm hold on the city. I wonder what steps Dr. Killick Millard would have decided to take in face of the threatening situation on June 28 last, when it was apparent that small-pox had appeared in the city, affecting children and adults alike, without any source or sources that could be traced. The only difference between the administration of the recent outbreak and previous ones was that a policy of general vaccination at the very outset was adopted and pressed, a measure fully justified by the results. —I am, etc.,

Glasgow A. S. M. MACGREGOR.

CO$_2$ Absorption Technique

SIR,—Dr. E. Y. Slaughter (Feb. 20, p. 232) enumerates some of the advantages of the CO$_2$ absorption technique, and concludes with the words, "The saving of gas is, of course, offset by the cost of the machine and soda-lime." This statement is so much at variance with practical experience that I have worked out the running costs of N$_2$O–O$_2$ anaesthesia with the old partial rebreathing technique and with CO$_2$ absorption.

Most types of continuous-flow apparatus have a "critical flow" of from 5 to 6 litres per minute mixed gases. This flow must be maintained or exceeded in order to keep the CO$_2$ concentration within reasonable limits. Assuming that the machine on the average delivers 5 litres a minute N$_2$O and 1 litre O$_2$, it will consume about 66 gallons per hour N$_2$O and 13 of O$_2$. A closed-circuit apparatus, on the other hand (taking Dr. Slaughter's own figures), will use about 500 c.cm. per minute N$_2$O and 250 c.cm. O$_2$, or 6.6 gallons N$_2$O per hour and 3.3 gallons O$_2$. The saving in gases by using the latter type of apparatus will, therefore, be 59.4 gallons N$_2$O and 9.7 gallons O$_2$ per hour.

If the two machines are in use for an average period of 5 hours on 300 days of the year, the saving by the closed-circuit apparatus will be 89,100 gallons of N$_2$O costing about £215 and 14,550 gallons O$_2$ costing £14. The total saving per machine per year will therefore be £229 less £25 for soda-lime (1 lb. at 1s. 8d. lasting about 5 hours), equalling £204. If the cost of adapting existing apparatus is £25, this would be paid off in under two months' use. I have not taken into consideration the lessened quantities of ether, trichlorethylene, or other adjuvants when used with the closed-circuit technique, nor the saving in labour and storage space by employing fewer and smaller gas cylinders. If a medium-sized hospital employing three old-type gas-oxygen machines changed over to the CO$_2$ absorption technique, the annual saving should be over £600, a figure which few lay committees would regard as negligible.

The calculations have been based on wholesale or "hospital" prices. The private anaesthetist enjoys a greater saving in running cost per hour owing to the higher prices he has to pay for gases. It would therefore appear to be incontestable that, on economic grounds alone, the closed-circuit technique marks a considerable advance in anaesthesia.—I am, etc.,

St Albans, Herts C LANGTON HEWER.

Desert Sores

SIR,—The article by Capt. H. M. Rapport (July 25, 1942, p. 96) is of the greatest interest to all serving with M.E.F. The fact that Capt. Rapport makes no mention of the simple treatment that I have found effective in a large number of cases is the excuse for this unavoidably belated letter.

My experience has been mainly with British and African troops. I have had no opportunity for bacteriological examination of my cases, but in my opinion, judging from the appearance and course of "desert sores," the condition is generally a streptococcal infection. It is not confined to troops serving in the desert. There was an enormous incidence during the mountain warfare of the Italian East African campaign. I feel that some-such term as "tropical service ecthyma" is better descriptive of the condition than "desert sore."

I have been unable to convince myself that dietetic insufficiency plays any great part in the causation of the disease. I have seen it widespread in troops on an adequate ration of fresh meat, green vegetables, and fruit. Nor have I been able to demonstrate an increase in the healing rate following the addition of ascorbic acid to the diet. I consider that there are three main factors in the aetiology of "desert sores": (1) Increased liability to trauma under Service conditions and when wearing tropical uniform; under trauma must certainly be included insect bites. (2) Lack of proper facilities for personal hygiene. (3) Flies, which probably act both as vectors of infection and as irritants to slight breaches of the skin surface.

Rest is of primary importance in treatment. This is perhaps exemplified by Capt. Rapport's fourth case. In my cases I try to secure local rest and protection by the use of elastoplast. The ulcers and surroundings are gently cleaned. Bleeding from the ulcers should be avoided. The adjacent skin is thoroughly dried. The ulcer is completely occluded with overlapping strips of elastoplast, each about 1/2 inch wide. I find the elastoplast adheres more firmly if so applied, and it also more adequately prevents the penetration of sand under the strapping. A bandage is applied over the strapping to render it more secure, and the patient is told to report back in five days, or earlier if the strapping does not remain firm. After five days I usually remove the strapping, gently clean the ulcer site, and repeat the elastoplast and instructions. In cases in which the strapping is still firmly fixed after this period it is not necessary to remove it. In most cases the ulcer is granulating healthily after the first application, and in a majority is well healed after three applications.

I have combined this treatment with powdering the ulcer with sulphanilamide, but I do not think this measure greatly quickens healing. I have treated a number of cases by powdering with sulphanilamide, covering with vaseline gauze, and bandaging. My results have been good, but apart from the discomfort of the bandage the method demands the inconvenience of a daily dressing. To my mind it is most important to avoid trauma to the ulcer. This is the reason for the vaseline gauze. Lotion dressings, unless they can be changed so frequently as to prevent drying and sticking, are to be deprecated. When dry their changing is inseparable from trauma and pain.

Apart from its successful results in my hands, the main advantages of the treatment are its comfort to the patient, its simplicity, and its economy of time. In all save very bad cases a patient under elastoplast treatment can take his position in the line and has not to attend sick parade daily or oftener. A dressing applied with bandages is uncomfortable and hampering at the best of times, and is especially so under active service conditions. In addition, I am convinced that the constant friction of a bandaged dressing exacerbates the condition of the ulcer. The bandage I use over elastoplast cannot cause friction, and it can be easily readjusted by the patient himself as often as necessary.

That some degree of immunity often follows streptococcal infections of the skin is a familiar phenomenon. I think the same may be said of "desert sore." In my experience the man who has recovered from an attack of "desert sores" is much less susceptible to the disease than a newcomer. As a footnote I would add that it is as well to consider the possibility in African troops of an old syphilitic taint in the case of persistent lesions.—I am, etc.,

HENRY RICHARDS.

Any Questions?

SIR,—Hearty congratulations on your new section "Any Questions"; may it grow in size as you suggest it will. I am sure all general practitioners will appreciate this type of thing. In your article introducing this section you sympathize with the "tired doctor faced with the toil of reading an article three or four pages long when what he really wants to know is how to get rid of that troublesome pain complained of by Mrs. X," but that statement is rather vague. He would not perhaps mind reading an article—however tired he may be—if it were of real interest to him. He certainly will not sit down and digest—or endeavour to do so—a long article (complete with statistics) showing the incidence of some rare and obscure disease, or the value of some ? vitamin on debilitated rats in the Far East, this latter presented with expensively produced photomicrographs! I am not minimizing the value of these articles, but surely they belong to the more specialized literature which the busy G.P. has not the time or perhaps the inclination to peruse. As you rightly point out, it is the everyday things of general practice—e.g., the treatment of chilblains, rheumatism, etc.—on which he requires brief but useful and guiding information on up-to-date methods. I am looking forward to this new section with great pleasure.—I am, etc.,

T. ASTLEY COOPER.

Obituary

R. H. JOCELYN SWAN, O.B.E., F.R.C.S.

We regret to announce the death on March 2, at the age of 66, of Mr. Jocelyn Swan, consulting surgeon to the Royal Cancer Hospital. The son of a medical man, Russell Henry Jocelyn Swan was educated at Wilson's School and Guy's Hospital. He took the M.B., B.S. of London University in 1898, gaining first-class honours in medicine. Four years later he took both the M.S. of London University and the F.R.C.S. At Guy's he was demonstrator in anatomy and biology, and held the post of house-surgeon and resident obstetric officer. He was also house surgical officer to St. Peter's Hospital for Stone, a post which determined the specialty which he pursued so successfully. He wrote numerous papers on diseases of the kidney, and contributed articles on genito-urinary diseases to French's *Index of Differential Diagnosis*. Swan was consulting surgeon to St. Paul's Hospital for Genito-Urinary Diseases, was on the editorial committee of the *British Journal of Urology*, and at one time was president of the Section of Urology of the Royal Society of Medicine. His other main interest was in cancer, and he was surgical registrar, assistant surgeon, surgeon, and emeritus surgeon successively to the Royal Cancer Hospital in Fulham Road. He published articles on such matters as sarcoma of the tongue, carcinoma of the breast, and tumours of the urinary tract. Mr. Swan served on the Grand Council of the British Empire Cancer Campaign. In the last war he was a temporary major in the R.A.M.C., and was mentioned in dispatches. He was surgeon to the Royal Herbert Hospital, Woolwich, and also to the American Red Cross Hospital for Officers. When the present war broke out he gave up private practice and took up duty as divisional surgeon at the E.M.S. hospital at Park Prewett, Basingstoke.

A colleague writes: Jocelyn Swan was a surgeon of first-class ability in many different "lines." Best known for his renal and all-round genito-urinary work—in which he was far more than merely a fine operator, but was most careful and thorough in investigation as well as of excellent judgment—he was also in the front rank in many other branches, as those who attended the practice of the Cancer Hospital knew very well. His operations for cancer of the breast were models of the best and most thorough technique of the times, and his gastric work was equally good. He knew when not to operate, which is one of the marks of a real surgeon, and his calm air of decision and invariable gentleness and courtesy in handling every type of patient always gained the confidence of those he was treating. In his day at Guy's (where he would surely have been a great acquisition to the staff) he had been a notably elusive rugger half-back, worthy of the best Guy's tradition; and he was also a pretty good golfer and more than average at lawn tennis. He had his share of adverse fortune: he lost his first wife by a very rare form of malignant disease not even mentioned in textbooks; and when he married again his second wife was stricken on their honeymoon with a serious disease which nearly cost her life and left her a paralysed invalid for many months.

C. H. CATTLE, M.D., F.R.C.P.

Consulting Physician, General Hospital, Nottingham

By the death of Dr. C. H. Cattle on Feb. 9, at the age of 87, Nottingham lost its oldest medical practitioner and a link with the latter half of the Victorian era. The son of a Wesleyan clergyman, Charles Henry Cattle was educated at a Wesleyan college and began his medical education at the Leeds Medical School, afterwards incorporated in the Leeds University. It was here that he became acquainted with Sir Clifford Allbutt, and a friendship arose which lasted throughout their lives. Cattle took his M.R.C.S.Eng. in 1876 and soon afterwards graduated M.B.Lond., proceeding M.D. in 1880. He was in general practice in Nottingham for some years, and was greatly helped at that time by Dr. W. H. Ransom, F.R.S., who was then senior physician at the General Hospital. He went on to obtain his M.R.C.P., and in 1908 he was elected a Fellow of that College. In 1901 he was appointed hon. assistant physician to the General Hospital, Nottingham, and he then became a consulting physician, which had always been his ambition and intention. He followed as full physician in 1906, and he was also physician to the Ransom Sanatorium for Tuberculosis. The whole of his professional life was spent in Nottingham, where he soon gained a high place in the esteem of his fellows, and also a large consulting practice.

Cattle made many contributions to medical literature, especially on affections of the heart and lungs. He took an active part in the discussions of the Nottingham Medico-Chirurgical Society, of which he was secretary for many years and, later on, president. Deeply interested in the affairs of his profession, he was a member of the B.M.A. for 63 years. A keen cyclist, he wandered over the greater part of England, Wales, and Scotland on a pedal machine, which he rode up to the age of 74. He was also a great walker, and kept this up till nearly the end. His library was well stocked with medical and general literature, as was only to be expected from one who read so extensively and found such solace in the best books. He had a retiring, kind, simple, and sympathetic nature, and no desire for publicity. His religion meant much to him. The high esteem and affection in which he was held was manifested by the large number, including many colleagues, who attended the memorial service.

JOHN LIONEL STRETTON, M.R.C.S., J.P.

We regret to announce the death at the age of 82 on Feb. 14 after a few days' illness of Dr. J. L. Stretton, honorary consulting surgeon to the Kidderminster and District General Hospital. Born at Kidderminster in 1860, John Lionel Stretton received his medical education at St. Bartholomew's Hospital, and qualified M.R.C.S. in 1881. In the following year he took the L.R.C.P. and the L.S.A. He was appointed assistant anaesthetist at St. Bartholomew's and was to have been resident gynaecologist and house-surgeon, but he returned home to join his father's practice. In 1882 he succeeded his father as an honorary surgeon to the Kidderminster Hospital and was an active member of the staff for 56 years. When he resigned at the end of 1938 he accepted the position of honorary consulting surgeon. He was president of the hospital from 1924 to 1937. His professional ability and administrative skill were of incalculable value to the hospital, and his work for it was a dominating factor in his life. His method of sterilizing the skin with iodine was described in the *Journal* in 1909 and 1910 and afterwards generally adopted. The most remarkable of his pathological specimens were exhibited before the war in the Wellcome Museum in London, where they are now in safe keeping. In 1936 Mr. Stretton gave his private nursing-home, with its equipment, to the hospital, to be used for paying patients.

He was a Justice of the Peace, and other offices he held included that of chairman of the Worcestershire Division of the B.M.A. in 1911, 1912, 1916, and 1920, and president of the Worcestershire and Herefordshire Branch (1914); chairman of the Local Medical Committee for the County of Worcester (1914-18); chairman of the Local Medical War Committee for the Worcester and Bromsgrove area (1939-42); chairman of the County of Worcester Local Medical and Panel Committee (1912-42); and president of the Kidderminster Medical Society. A man of sound judgment and strong views, he was inflexible in upholding what he considered right. His guiding principles were self-sacrificing devotion and unswerving loyalty to his ideals, his profession, and his friends. He leaves a widow, two sons, and a daughter; the younger son, John W. Stretton, F.R.C.S., is senior honorary surgeon to the Kidderminster Hospital, and thus represents the third generation of his family on the staff.

Dr. H. NEVILLE CROWE writes: I knew of Dr. Lionel Stretton before I started in practice in 1909, and got to know him personally when I became honorary secretary of the Worcester Division of the B.M.A. in 1909; I was instrumental in securing his appointment as chairman of the Division in 1911 and 1912, at the time the Insurance Act came into force. I was impressed with his grasp of the business and his conduct of many difficult meetings. He was chairman of many meetings of which I was a member after this, and I got to know his true worth. Later I was appointed radiologist to the Kidderminster General Hospital and came to appreciate his professional skill more fully. He lived for his hospital and was an example to all his colleagues. He was beloved by all his patients and by all who worked with him for his sterling qualities, his devotion to duty, and his straightforwardness.

Dr. U. W. N. MILES sends the following appreciation: When I first knew Dr. J. L. Stretton, in 1897, he was engaged in the extensive country practice which he inherited from his father. He was even then recognized as the leading member of the profession in this part of Worcestershire, and we general practitioners turned to him for help in all our difficulties—medical, surgical, and obstetrical—and he never failed to give us prompt and skilful assistance. This experience gave him a very broad outlook when, later, he devoted himself entirely to surgical work, and made him a valuable chairman of the various professional societies over which he presided. For twenty years, from 1916, I had the privilege of acting as his anaesthetist and can bear witness to his great skill as a surgeon. He was a man of tireless energy, who never got flurried in any emergency, and who was always considerate and courteous to his assistants and nurses. He was a true friend and adviser to all younger members of the profession in this district in many things beside their professional difficulties. He was spoken of as "Father" in his hospital and well deserved that tribute of respect and affection, not only from his nursing staff but from all his professional colleagues.

G. B. DIXON, M.R.C.S., L.R.C.P.

The death of Dr. G. B. Dixon has removed one of the most distinguished of the now diminishing band of men who took up duty as tuberculosis officers on the initiation of the N.H.I. Act just over thirty years ago. Godfrey Brookes Dixon was a Cumbrian by birth, and received his medical education at Charing Cross Hospital, where as a student he won the gold medal in medicine. Under the influence of Dr. Mitchell Bruce, to whom he was house-physician, his interest was directed to tuberculosis early in his career, and soon after qualifying in 1901 he spent the best part of two years at Davos in Switzerland studying the treatment of tuberculous patients there. He then became assistant medical officer and later superintendent of the Walton Infirmary, Liverpool, where he was one of the first to institute the open-air treatment of patients suffering from pulmonary tuberculosis in a Poor Law infirmary. Later he was for a time assistant medical officer at the Vale of Clwyd Sanatorium. Subsequently he spent five years in general practice as assistant to his cousin, Dr. J. H. Salter of Tolleshunt D'Arcy in Essex. The turning point in his career came in 1910, when, at the age of 33, having had to retire from general practice following an attack of pneumonia, he was appointed medical superintendent of the Birmingham Municipal Sanatorium at Yardley Road, then on the outskirts of the city. In 1912 he intended to apply for the post of superintendent of the Brompton Hospital Sanatorium at Frimley, but was dissuaded from doing so by Dr. John Robertson, medical officer of health for Birmingham, who recognized his great ability and insisted on retaining his services as tuberculosis officer for Birmingham. From small beginnings the tuberculosis service of the city became built up around his person and under his guidance, and for thirty years he performed the double duty of superintendent of a sanatorium of over 300 beds and chief tuberculosis officer to a city of 1,000,000 population with the supervision of three other sanatoria.

Dixon was one of those rare individuals who are both good clinicians and sound administrators. In all he did he was extremely painstaking. He possessed a real flair for organization, no detail being too small to escape him. Though never averse from new ideas he liked first to assure himself that they were sound. His advice on administrative problems was frequently sought by tuberculosis officers and medical officers of health of other localities as well as by the Ministry of Health. In later years it gave him much gratification to be elected to serve on the Council of the National Association for the Prevention of Tuberculosis and on the Joint Tuberculosis Council, and he took great interest in this work. The best tribute to his reputation as a tuberculosis physician among the medical profession in Birmingham is to be found in the fact that he was repeatedly consulted by medical men on behalf of themselves and their families. He had a high sense of duty and never spared himself in doing what his conscience dictated; no community could have had a more faithful public servant. Though always a stubborn fighter for what he believed to be right, he was an extremely sensitive man, and was apt to feel acutely things that might not have affected one less sensitive. He was a man of outstanding personality, and his passing leaves a gap that will be hard to fill.

J. R. T.

Dr. JAMES BRAILSFORD writes: Tuberculosis officers when first appointed had no easy task to establish their position. G. B. Dixon was one of the first to be appointed, and his triumph over the many difficulties which I know to have been put in his path redounds to his credit. The care, patience, and skill which he brought to bear during the thorough clinical and scientific investigation of the patients referred to him enhanced his prestige with his colleagues and brought him the good will of his many patients. He was able to assess the value of diagnostic and therapeutic procedures, and applied them accordingly. He commanded respect from all with whom he was associated, and was ready at all times to give help to all that sought it.

We regret to announce the death on Feb. 7 of Dr. JOHN STEWART of Crosshill, Glasgow. He was born at Lochgilphead, Argyllshire, in 1862, and educated at the Highland Memorial School, Glasgow, and at Glasgow University, where he graduated M.B., C.M. (with commendation) in 1886, proceeding M.D. in 1891. In 1932 he was elected a Fellow of the Royal Faculty of Physicians and Surgeons of Glasgow. Dr. Stewart practised in the south side of Glasgow for over 50 years, and was a member of the Local Panel Committee. He had also been president of the Glasgow Southern Medical Society. He took a keen interest in the Victoria Infirmary, of which he was a governor for 30 years. Dr. Stewart had been a member of the B.M.A. since 1894, and represented his constituency at the Annual Representative Meeting held at Leicester in 1905.

We regret to record the death recently of Dr. GEORGE BRUCE PEARSON of Buckingham, at the age of 72. Educated at Guy's Hospital he qualified in 1901, and after a short period as an assistant at Retford he went to Buckingham, where he continued to practise until his death. Throughout these years he was prominent in the life of the town. He was medical officer to the Buckingham Guardians Union, to the Fire Brigade, and to the Police. As medical officer of health to the rural district he took special interest in helping to maintain a clean milk supply and in the arrangements for main water supply to surrounding villages. For a number of years he was divisional surgeon to the St. John Ambulance Association, and was especially proud of the fact that during this time his women's team won the Perrott Shield in two successive years. For 30 years he was an enthusiastic chairman of the local cricket club. He had been a member of the British Medical Association since 1903, and was chairman of the Buckingham Division in 1926–7. An original member of the Bucks Local Medical and Panel Committee, he attended their meetings regularly and took the chair on many occasions. During the last war he served with the Royal Bucks Hussars in Gallipoli, where he was wounded, and later in Palestine and Egypt. As a general practitioner of the best type and as a genial host he will be missed by his patients and his friends.

A colleague writes: Many will think of him not merely as their doctor but above all as their friend, for he was a faithful friend. With a hatred of sham and pretence, he could be disconcerting in the plainness of his speaking and opinion, which he never concealed from anyone. Probably his directness and plain speaking concealed his genuine kindness of heart from some who did not understand it. But no one who was in real trouble or anxiety ever went to him in vain, for he treated all alike. To the poorest of his patients he was the same as to the richest; they were all of them important for all of them needed his help.

Medical Notes in Parliament

Scottish Medical Advisory Committee

Replying to Commander Galbraith on Feb. 16 Mr. JOHNSTON said that by long-established practice the Department of Health for Scotland had from time to time sought outside expert advice upon special medical problems. He found in the profession a general desire for a regularly constituted committee to advise the Department on the many problems with a wide medical interest which confronted the country. He had therefore set up a medical advisory committee whose terms of reference were "to advise on the medical aspects of problems relating to the health of the people." Its members were: Sir John Fraser (chairman), Prof. E. P. Cathcart, Dr. G. Matthew Fyfe, Dr. Catherine Harrower, Prof. James Hendry, Col. T. D. Inch, M.D., Dr. D. Dale Logan, Sir Alexander Macgregor, Dr. E. K. MacKenzie, Dr. A. F. Wilkie Millar, Dr. R. Richards, Sir John Orr, Prof. A. Patrick, and Prof. Sydney Smith.

Mortality among Mental Patients

Mr. ERNEST BROWN on Feb. 18 furnished the following tables of deaths in mental and mental deficiency institutions and the percentage to total population of those institutions:

I. *Mental Institutions*

Year	No. of Deaths	Percentage
1938	9,136	6.57
1939	10,207	7.30
1940	11,623	8.38
1941	12,598	9.22

II. *Mental Deficiency Institutions*

Year	No. of Deaths	Percentage
1938	442	1.24
1939	499	1.33
1940	636	1.65
1941	734	1.87

The institutions included in Table I are county and borough mental hospitals, registered hospitals, licensed houses, hospitals and nursing homes approved under the Mental Treatment Act, 1930, naval and military hospitals, and the Criminal Lunatic Asylum, Broadmoor. Those included in Table II are the State institution, certified institutions, certified houses, and approved homes. Percentages are based on the daily average number of patients resident.

National Institute for Medical Research and M.R.C.

Sir ERNEST GRAHAM-LITTLE asked on Feb. 24 whether the Lord President of the Council was aware that the recently appointed director of the National Institute for Medical Research, who succeeded in that office a Nobel Prize winner in medicine, possessed no medical qualification and had no medical training. Sir Ernest asked the present composition of the Medical Research Council and whether there was adequate representation of clinical medicine on that body. Sir JOHN ANDERSON replied that the new director of the National Institute for Medical Research was a distinguished investigator in an important branch of medical science, who had already been head of a department in a medical school of the University of London. He was not medically qualified, but the clinical departments of the Medical Research Council were not comprised in the National Institute. The present members of the Medical Research Council were: Lord Balfour (chairman), Sir William Goodenough (treasurer), Sir Charles MacAndrew, Prof. T. R. Elliott, Sir Wilson Jameson, Prof. S. P. Bedson, Mr. E. Rock Carling, Prof. F. C. Bartlett, Prof. E. D. Adrian, Sir Henry Dale, and Prof. D. Keilin. The principal subjects represented by the 8 members appointed in respect of their scientific qualifications were clinical medicine, surgery, preventive medicine, pathology and bacteriology, pharmacology, physiology and neurology, biochemistry, and psychology. Sir John was satisfied that this provided a well-balanced representation of the different branches of medical science.

Rehabilitation in the Army

Introducing the Army Estimates on Feb. 25, Sir JAMES GRIGG said he did not mention the health of the troops because in that matter the Army's history for the past year had been a blank, to the immense credit of the Army medical and nursing services.

Sir THOMAS MOORE raised the question of the hospital treatment of the Home Guard officer; he was turned out of officers' convalescent hospitals. A document issued by the War Office on Oct. 13, 1942, said Home Guard officers must be treated as private soldiers and relegated to the nearest ordinary hospital. Mr. HENDERSON said it would not be consistent with the basis of the Home Guard if different treatment were given to Home Guard officers compared with other members.

Major NEVEN SPENCE stated that the chief worry of the serving soldier was the doctor's bill when there was sickness in his home. Sir James Grigg should arrange forthwith for free medical treatment of all dependants. It would be tremendously popular with young married soldiers.

Mr. ARTHUR HENDERSON spoke on rehabilitation carried out both in hospitals and at military convalescent depots. The first stage of remedial treatment was given in the physiotherapy department of the hospital. It consisted of massage, exercises, and radiant heat and ultraviolet-ray treatment. When hospital treatment was no longer necessary the patient was sent to a military convalescent depot and physical fitness was restored by graduated exercises and training. There were 13 military convalescent depots in the United Kingdom with 11,078 beds for soldiers. For rehabilitation of cases of neurosis a unit of 200 hospital beds and 600 convalescent beds had been established outside Birmingham. Success had attended the establishment of two centres for dealing with men with remediable defects such as curved spine or flat feet, and with men who were physically under-developed when they joined the Army. At one centre about 80% were up-graded to A1. It had been decided to establish four other centres.

Beveridge Report

During the resumed debate on the Beveridge report on Feb. 25 Lord ADDISON said that 23 years ago, when he was Minister of Health, Lord Dawson, with other medical men, reported to him upon an agreed scheme for the establishment of clinics, centres for early diagnosis, minor aids in the treatment of eyes and ears, and other services. That showed how slowly the country moved. A little had been done in that respect thanks to the energy and work of the medical profession, but if ever a subject were ripe for action it was this. He hoped the Government would instruct the Minister of Health and his colleague in Scotland to make progress with this part of the scheme. Lord RUSHCLIFFE considered that if the Beveridge report was put into the hands of a Government draftsman as it was, it would be outside his power to draft a Bill carrying it into effect. A universal health service was indissolubly bound up with the kind of scheme proposed by Sir William Beveridge, and health insurance was the core of the whole scheme. Until Parliament had ascertained what it was going to do with health, and how the health service could be fitted into the insurance proposals, it could not proceed further. Difficult and far-reaching questions between nurses, doctors, hospitals, and so on must be settled before they could begin to consider how to frame the legislation.

Lord SNELL said the Beveridge report, after a searching debate, emerged with the general approval of Parliament, of the Government, and of the nation. Between 80 and 90% of the report had been approved by the Government.

Venereal Diseases: Publicity Campaign

Mr. DAVID ADAMS inquired on Feb. 25 whether the propaganda campaign for the prevention and elimination of venereal disease would include a national appeal to all parents and guardians of children to instruct them in an elementary knowledge of sex and the natural functions of the body. Mr. BROWN said that at present he proposed to leave such action to the initiative of parents, but the Central Council for Health Education arranged sex education talks to parents and young people at the request of local authorities, local education authorities, and youth organizations. The campaign also included pamphlets addressed to adolescents distributed through local authorities and in other ways.

The Services

The M.C. has been awarded to Capts. S. M. P. Conway, D. Macrae, J. J. McCall, and P. Unwin, R.A.M.C., in recognition of gallant and distinguished services in the Middle East.

CASUALTIES IN THE MEDICAL SERVICES

Lieut. ROBIN GERALD SPICER, R.A.M.C., who was killed on active service last month, was born on Sept. 12, 1917, the youngest son of the late Mr. G. B. Spicer, C.B., and of Mrs. Spicer of Ardingly, Sussex. He received his professional education at the London Hospital, qualifying M.R.C.S., L.R.C.P. in 1942. Before entering the R.A.M.C. in Oct. last he held appointments at Warley Woods Hospital, Brentwood, and Addenbrooke's Hospital, Cambridge. He was married on Jan. 23 at St. Giles Cathedral, Edinburgh, to Joan Elizabeth, the younger daughter of the late Dr. Percy Stewart and of Mrs. Stewart of Edinburgh.

Capt. THOMAS PICTON MYLES, R.A.M.C., who died in India in Nov., 1942, was educated at the University of Cambridge and at St. Mary's Hospital, qualifying M.R.C.S., L.R.C.P. in 1936. He also took the M.B., B.Chir. degrees in 1937 and the D.O.M.S. of the English Royal Colleges in 1939. After holding house appointments at Sheffield Royal Infirmary and St. James Hospital, Balham, he entered the R.A.M.C. as lieut. in Sept., 1937, and was promoted capt. a little over a year later. He joined the B.M.A. in 1937.

Prisoners of War.—Fl. Lieut. R. F. Braithwaite, R.A.F.V.R., Wing Cmdr. C. W. Coffey, R.A.F., Squad. Ldr. J. A. MacCarthy, G.M., R.A.F. Fl. Lieut. N. J. W. Thompson, R.A.F.V.R.

Missing.—Lieut. J. G. Warren, R.A.M.C.

Universities and Colleges

UNIVERSITY OF OXFORD

An election of two members of the Board of the Faculty of Medicine will be held on June 9. The members elected will come into office on the first day of Michaelmas Term, 1943, and will hold office, the senior for two years and the junior for one year, from that day.

The general medical electorate consists of all Oxford graduates in medicine who are members of Convocation. The Board of the Faculty of Medicine includes two members elected by the general medical electorate who must be members of that body and of whom one at least must be a person engaged in teaching one or more of the clinical subjects of the Faculty.

Nominations of duly qualified candidates for election will be received by the Secretary of Faculties at the University Registry up to 10 a.m. on May 19. Each nomination must be signed by six members of the general medical electorate, and no candidate will be eligible whose nomination has not been received by that date.

In a Congregation held on Feb. 27 the following medical degrees were conferred:

B.M., B.CH.—J. M. Garvie, R. I. K. Elliott, D. G. T.-Hicks, J. C. Prestwich (in absence).

UNIVERSITY OF CAMBRIDGE

At a Congregation held on Feb. 26 the following medical and surgical degrees were conferred:

M.D.—A. G. Cross, R. H. A. Swain (by proxy), F. H. King (in person).
M.B., B.CHIR.—R. B. Meyer, G. M. Barrett, S. C. H. Hood, D. E. C. Whittome, P. N. Cunliffe, G. C. L. Roberts (all by proxy).

W. M. Beattie has been examined and approved for the degree of M.Chir.

Medical News

Sir Henry Dale, P.R.S., will deliver a series of lectures on "Chemistry in Modern Medicinal Treatment" at the Royal Institution, 21, Albemarle Street, W., on Tuesdays, March 16, 23, and 30 and April 6, at 3 p.m.

Sir Alfred Egerton, F.R.S., will give a discourse on "Warmth and Comfort Indoors" at the Royal Institution, 21, Albemarle Street, W., on Friday, March 19, at 5 p.m.

The lecture by Prof. H. Dingle (Professor of Natural Philosophy at the Imperial College of Science) on "Space and Time in Modern Physics" (postponed from Jan. 22 owing to the sudden illness of the lecturer) will now be delivered at the British Institute of Philosophy on Friday, March 19, at 5 p.m. Cards of admission may be obtained free of charge from the Director of Studies at University Hall.

A joint meeting of the Therapy Section of the Faculty of Radiologists with the British Institute of Radiology and the Faraday Society will be held at 32, Welbeck Street, W., on Friday, March 19, at 2 p.m., when there will be a discussion on "The Physical and Chemical Action of Radiations in Relation to their Biological Effects," to be opened by Drs. D. E. Lea, C. B. Allsopp, and J. S. Mitchell.

A meeting of the Middlesex County Medical Society will be held at North Middlesex County Hospital, Silver Street, Edmonton, N., on Wednesday, March 17, at 3 p.m., when clinical cases will be demonstrated and discussed. Visitors, especially members of the American and Canadian Forces, will be welcome.

A second conference on x-ray analysis, arranged by the Institute of Physics, will be held at Cambridge on April 9 and 10. The provisional programme includes a lecture on future developments in x-ray crystallography by Prof. J. D. Bernal, and discussions on quantitative treatment of powder photographs and the fine structure of x-ray diffraction. There will also be a report on the progress made in the preparation of an index to x-ray diffraction photographs. Further particulars may be obtained from the Secretary of the Institute of Physics, the University, Reading.

The 63rd annual meeting of the Mental After Care Association will be held at Burlington House, Piccadilly, London, W.1, on Tuesday, March 23, at 2.45 p.m.

A sessional meeting of the Royal Sanitary Institute will be held at 90, Buckingham Palace Road, S.W., on Tuesday, March 23, at 2.30 p.m., when a paper on "Mosquito Problems in Static Water Tanks" will be read by Mr. P. G. Shute, Adviser on Mosquito Control to the Ministry of Health.

The Ministry of Health has decided to effect certain changes in the salaries of whole-time officers of the E.M.S. As from Feb. 1 last officers in the £350 grade are to be placed on a range of salary from £350 to £450, those at £550 a year on a range between £550 and £650, and those at £800 a year on a range of £800 to £900, the amount in lieu of emoluments remaining at its present figure of £100.

Mr. George H. Macnab, honorary assistant surgeon, Westminster Hospital, is to be Dean of the hospital in succession to Sir Adolphe Abrahams.

The Socialist Medical Association, at a meeting held on Feb. 28, considered its policy in view of the Government's decisions on the Beveridge report. The following resolutions were unanimously adopted: "(1) The S.M.A. reiterates its welcome to the Beveridge report as an effort to deal with two factors in the causation of ill-health: the existence of poverty and the absence of an organized health service. It views with regret, therefore, the failure of the Government to implement the report. It wishes to emphasize that from the health point of view the provisions of the report, based as they are on subsistence and not on optimum dietary standards, cannot be lowered. The acceptance of Assumption B is warmly welcomed. We urge that 'the restoration of the sick is a duty of the State and the citizen, prior to any other consideration,' as suggested in the report, should be accepted as the keynote of the service which the Minister of Health is discussing. The efficiency of that service in the care of health, and not a doctrinaire belief in the necessity of preserving the voluntary hospital principle or any other existing service, must be the basis of a comprehensive National Medical Service. (2) This meeting of the S.M.A. believes that there should be one standard of medical service for all beneficiaries in a comprehensive National Medical Service, and that doctors employed by this service should not be permitted to accept private fees."

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* there was a further rise during the week in the notifications of measles, 907, but a drop in the other infectious diseases—scarlet fever 151, acute pneumonia 143, diphtheria 67, cerebrospinal fever 28, whooping-cough 15.

The largest variations from the totals of the previous week were: for scarlet fever a fall of 25 in London and a rise of 21 in Lancashire; for diphtheria a fall of 21 in Yorks West Riding and a rise of 14 in Lancashire; for whooping-cough a rise of 32 in Staffordshire and a fall of 29 in Yorks West Riding.

The fall in the notifications of acute pneumonia was the result of experience in the North. In the South, including London and the South-Eastern, South-Western, and South Midland counties, there was a slight rise from 323 to 345 cases. The largest decreases were those of Lancashire 55, Yorks West Riding 37, and Staffordshire 35.

The only feature of note in the returns for dysentery was an outbreak involving 13 persons in Lincolnshire, Caistor R.D.

The incidence of measles has mounted steadily during the past month, and the total of 18,215 cases reported during the week is the largest weekly total since notification of this disease began in the autumn of 1939. The biggest rises during the week were those of Durham 280, Sussex 210, Leicestershire 128, Surrey 127, Devonshire 115, Glamorganshire 138. In several counties decreases were recorded, the largest being Yorks North Riding 293, Middlesex 134, and Cheshire 106.

In *Scotland* the rise in the notifications of measles and of whooping-cough was due to the experience of Glasgow, with an increase of 44 for measles and 24 for whooping-cough.

In *Eire* the returns were dominated by a few areas: 29 of the 54 cases of whooping-cough and 16 of the 21 of measles were reported from the rural district of Enniscorthy, Co. Wexford. Half the notifications of diphtheria were from the cities of Dublin and Cork, and half the cases of scarlet fever from the city of Dublin and Balrothery R.D., Co. Dublin.

The Week Ending February 27

The notifications of infectious diseases in England and Wales during the week included the following: scarlet fever 1,934, whooping-cough 1,786, diphtheria 813, measles 20,082, acute pneumonia 1,373, cerebrospinal fever 103, dysentery 96, paratyphoid 6, typhoid 3. Influenza was the cause of 87 deaths in the great towns.

No. 7

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Feb. 20.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Disease	1943 (a)	(b)	(c)	(d)	(e)	1942 (Corresponding Week (a)	(b)	(c)	(d)	(e)

Rate per 1,000 total births (including stillborn)			42					55		

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes paratyphoid A and B for Northern Ireland.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.
ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.
Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.
ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.
TELEPHONE No.—B.M.A. and *B.M.J.*: EUSTON 2111.
TELEGRAPHIC ADDRESSES.—EDITOR, *Aitiology Westcent, London;* SECRETARY, *Medisecra Westcent, London.*
B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Cramp in Arteriosclerosis

Q.—*An elderly male patient suffers severely almost every night with cramp in the leg muscles. For a time relief was obtained from the suggestion given in an earlier number of the* JOURNAL—*to pinch firmly the nearest tendon. Is anything likely to help this sudden and distressing symptom? The man is an arteriosclerotic with nephritis and asthma.*

A.—The complicated clinical picture makes a simple answer difficult. Bathing the legs in hot saline (1 teaspoon to the pint) for 15 minutes before retiring may help. Nicotinic acid, 50 mg. daily, is also worth trying.

Treatment of Dysmenorrhoea

Q.—*Is there any really effective cure for dysmenorrhoea? I have several fairly severe cases. In the past some of my patients have been treated by dilatation of the cervix—usually with disappointing results. Remedial exercises have relieved others; but there seems to be a type of case which is not relieved by any treatment except opiates, which are undesirable.*

A.—Dysmenorrhoea is a symptom and not a disease. For this reason no one method can be effective in all cases and only a minority will respond to dilatation of the cervix. When pain is hypogastric in site, begins with the onset of the menstrual flow, and is associated with a moderate loss and either acute anteflexion or retroflexion of the uterus, the response to dilatation is likely to be satisfactory. If the dysmenorrhoea occurs shortly after puberty, is hypogastric in site, and is associated with a poorly developed uterus and scanty flow, intermittent oestrogen therapy is the most hopeful line of treatment. Stilboestrol can be used in doses of 1 mg. for 14 days, beginning as soon as the period ends. It should be continued after subsequent periods for 3 months or longer. When there is no evidence of genital hypofunction good results may be obtained by the injection of adrenaline in oil with the onset of pain, or by the combination of dilatation of the cervix with injection of the paracervical plexus with 80% alcohol. This should not be done by the occasional operator. Acquired dysmenorrhoea beginning in later life is usually an indication of pelvic inflammation, congestion, or endometriosis. The pain is likely to be in the iliac fossae or back, indicating adnexal disease. The subject is not easy, and good results can be obtained only if cases are carefully selected and appropriately treated. In all, attention to personal hygiene is of paramount importance.

Morphine and Shock

Q.—*Does the injection of morphine increase or lessen shock after bomb injuries?*

A.—The main action of morphine is to decrease the perception of pain; the next most important effect is its depressant action on the respiratory centre. Its action in "shock" depends on the dosage and route of administration, as well as on what is meant by this abused and almost meaningless term.

If pain is severe and just enough morphine be given to relieve it (gr. 1/4 or 1/2 subcutaneously), this will not adversely affect any peripheral circulatory failure that may be present due to decreased blood volume from haemorrhage or plasma loss—that is, in relation to the patient as a whole it will be beneficial; but will not take the place of the transfusion of blood or plasma which is essential to replace that lost. If a much larger dose be given, and especially if given in the later stages of peripheral circulatory failure, when there is anoxia, it may be harmful because of its depressant effect on the respiratory centre. The indiscriminate use of morphine for "shock," which in most cases so diagnosed during a blitz is largely fright, is to be deplored; *it should be used to relieve pain.*

The route of administration is important. With a severe degree of peripheral vasoconstriction uptake from subcutaneous tissue is slow, and it is better given intramuscularly, or by placing two 1/4-gr. tablets beneath the tongue, or by giving gr. 1/6 diluted to 1 or 2 c.cm. with saline intravenously.

Too Much Iron?

Q.—*Is it possible to give too much iron, especially to children? And if so, what are the symptoms?*

A.—The only ill effect of excessive dosage of iron which appears to be at all common is the formation of intestinal concretions with consequent obstruction of the bowel. In children there is the special risk of precipitation of phosphorus as insoluble ferric phosphate in the intestine and consequent liability to rickets. Iron encephalopathy with convulsions has been described, but it is generally believed to be extremely rare. Nevertheless, it seems unwise to administer unnecessarily large doses of iron, and it is a growing practice to give ferrous salts for routine therapy in pharmacopoeial dosage only, and to devote special individual attention to cases in which this dosage seems inadequate.

INCOME TAX

Cessation of Appointment

C.'s appointment and salary ceased at the end of April, 1942. Tax had been deducted from the payments made to him, but the collector is now claiming a sum of £100 as not having been included in the deductions.

*** The tax deducted in the year ended Oct. 31, 1941, was that due for the financial year ended April 5, 1941, and the tax deducted from Nov. 1, 1941, to the end of April, 1942, say £x, was in respect of the tax for the year ended April 5, 1942. C. is now liable to account for the excess of the full tax for the latter year over £x, and any liability in respect of the amount earned between April 5, 1942, and the date of cessation.

Depreciation of Car

"A. B. C." used two cars up to May 1, 1942, on which date one of the cars was left unlicensed. Can he claim the depreciation allowance on that car? Also, if he were to sell the car for £450, which would exceed the written-down value, and buy another car for £900, would he be entitled to the allowance on £900?

*** The allowance provided is for depreciation by reason of "wear and tear," and no allowance is therefore due for the period when a car is unlicensed and out of use. The answer to the further question is that in such circumstances an allowance would be due based on the cost price of £900.

LETTERS, NOTES, ETC.

Liq. Ferri Perchlor. for Sore Throat

Dr. RALPH JONES (London, W.11) writes: I used frequently until the introduction of the sulphonamides liq. ferri perchlor. (with or without pot. chlor.) for sore throats. Lately I had three patients—one adult and two children—who could not take any form of sulphonamide without severe nausea and even vomiting. I gave these patients liq. ferri perchlor. (alone), and they cleared up very quickly. I did not take a swab of the adult patient's throat, but I did of those of the children, and in each case haemolytic streptococci were found. I should like to mention this for the benefit of those who may have forgotten or never tried this very old remedy.

Methaemoglobin in Normal Human Blood

Emeritus Prof. C. R. MARSHALL (Burley-in-Wharfedale) writes: In the report on haemoglobinometry by the subcommittee of the Committee on Traumatic Shock (Feb. 20, p. 209) the discovery of methaemoglobin in normal human blood is ascribed to Ammunsen in 1941. The first announcement of the presence of methaemoglobin in normal human blood was made by Wilfrid Marshall in the *Journal* of Jan. 16, 1932 (p. 98). He suggested that a balanced state exists, a minute concentration of methaemoglobin being in equilibrium with the oxyhaemoglobin of normal blood.

Medicine and Pharmacy in Other Countries

Dr. D. OCKMAN (Kearsley) writes: Dr. K. E. Barlow's letter (Feb. 6, p. 178) describing the pre-war chemist's shop in Denmark will be a revelation to those practitioners who, like myself, have not been able to observe at first hand the medical arrangements in other countries. Certainly it seems that what some people would regard as an unattainable medical Utopia for this country appears to be the ordinary normal state of affairs for Denmark. Perhaps our excessive insularity will be democratized by a period of Allied occupation of Europe, with intimate co-operation in the organization of medical relief, etc. In the meantime could we not have some regular information, like Dr. Barlow's, on the minutiae of medical arrangements in other countries as an aid to our own plannings?

BRITISH MEDICAL JOURNAL

LONDON SATURDAY MARCH 20 1943

THE PRESENT STATUS OF AMINOACRIDINE COMPOUNDS (FLAVINES) AS SURFACE ANTISEPTICS

BY

C. H. BROWNING, M.D., F.R.S.

(From the Bacteriology and Pathology Department of the University and Western Infirmary, Glasgow)

Infected war wounds again demand efficient chemotherapy as an adjunct to surgery; and while fulfilment of the high promise of penicillin waits on ample supplies, limitations in the performance of the sulphonamide series present themselves (Spooner, 1941; Francis, 1942; Mitchell and Buttle, 1942). The last-named workers have now returned to proflavine. Acriflavine and its precursor, proflavine (salt of 2:8-diaminoacridine), were introduced by us in 1917 as surface antiseptics because—they are powerfully bacteriostatic towards the important pyogenic organisms; serum does not diminish this action, although blood somewhat reduces it and pus greatly; toxicity for the body as a whole is not high; they are comparatively unirritating; and phagocytosis is little interfered with. It is appropriate to review briefly the present status of the aminoacridine group of drugs ("flavines") and possibilities of future improvements in them. Experimental results will be stressed, since patients should be subjected to new compounds only after their action has been closely studied in the laboratory. Further, experiments can be duplicated with the minimum of variation, which is difficult clinically.[*] When drugs with outstanding properties are discovered in the laboratory it remains for clinical skill to utilize them to full advantage.

Antiseptic Action

The diaminoacridine compounds proflavine and acriflavine are antiseptics whose action is intensified rather than reduced when the medium contains serum (Browning and Gilmour, 1913). This feature distinguishes them from all the powerful older antiseptics. When surgical experience after 1914 clamoured for improved treatment, these antiseptics were studied anew and proved highly potent. In serum, concentrations of 1:100,000 to 1:200,000 sterilize *Staphylococcus aureus* and typical *B. coli,* and in dilute peptone water 1:200,000 and 1:20,000 respectively. *Streptococcus pyogenes* is even more susceptible. Such high values are attained slowly, after 24 hours' contact—bacteriostatic action. However, brief contact with the drug, short of producing death, reduces the virulence of the organisms. *B. pyocyaneus, B. proteus,* and certain atypical *B. coli* may be highly resistant. Enhancement of antiseptic action is not displayed in a medium with only a low concentration of serum (10%). Although action is increased at a slightly alkaline *p*H, this may not entirely explain the serum effect. In defibrinated blood the killing rate is slowed (Rubbo *et al.,* 1942); nevertheless there is powerful antisepsis. Pus greatly reduces antiseptic action, although not invariably (Gay and Morrison, 1921).

Acriflavine of commerce usually contains some of its precursor, proflavine; but mixtures of the two in varying proportions differ little in antiseptic action (Berry, 1941). These dyes are strongly fixed by tissues and cotton fabrics, etc.: thus after 3 minutes' soaking in 100 c.cm. of acriflavine 1:1000 the fluid expressed from an average 5-g. gauze swab contains 1:1600 of the antiseptic; with 1:5000 the expressed fluid contains 1:9000 (Graham). In applying wet dressings allowance must be made for this.

Recently Albert *et al.* (1938) and Rubbo *et al.* (1942) have introduced potent new acridine antiseptics, especially 2:7-diaminoacridine and 5-aminoacridine, the latter having the great advantage of being non-staining.

Action on Cells and Tissues

Toxicity for the Animal as a Whole.—Toxicity of a drug often varies remarkably according to the mode of application; a striking illustration is the poisonous action of iron parenterally, as compared with its innocuousness in the alimentary tract. Amounts of antiseptics likely to be absorbed from wounds should not be harmful to the body as a whole. On subcutaneous injection into mice the "average lethal dose" of proflavine which causes the death of 50% of the animals in 2 to 3 days is 0.2 g. per kg. of body weight; of acriflavine, 0.05 g. (Albert *et al.,* 1937). Accordingly, even the latter is not "a substance of great toxicity to animal tissues." In the treatment of gonorrhoea intravenous doses of 0.1 g. thrice weekly (Jausion *et al.,* 1931)[†] or 10 doses each of 0.04 to 0.08 g. at 2- or 3-day intervals (Assinder) have been well tolerated. These amounts are equivalent to 40 to 100 c.cm. of 1:1000 solution; thus toxic damage in man from acriflavine or proflavine absorbed from wounds has not occurred. Skin idiosyncrasy has been met with, although very rarely (Young and Hawking). 2:7-diaminoacridine is less toxic for mice than proflavine, and 5-aminoacridine is intermediate between proflavine and acriflavine. At the site of injection of flavines into the *closed* tissues necrosis tends to occur with the higher concentrations, hence care should be exercised in this method of administration.

Epithelium.—Irritation of the rabbit's conjunctiva is very slight after 3 minutes' contact with 1:50 proflavine solution or 1:150 acriflavine; in contrast, brilliant green 1:1000 is irritating, which corresponds with its effect on the human urethral mucosa. By this test the suitability of drugs for the local treatment of gonorrhoea was estimated. However, since irritation of wound surfaces is not caused by brilliant green, such results again emphasize the importance of the mode of application.

Brain.—Russell and Falconer (1941) exposed part of a cerebral hemisphere in rabbits and applied to the surface for 10 minutes "lintine" soaked in a solution of antiseptic; simultaneously 0.1 c.cm. was injected into the cortex. 1:1000 solutions of proflavine and 2:7-diaminoacridine in isotonic saline buffered at a *p*H of 6.2 were practically harmless, like neutral isotonic saline, judging by histological examinations made 1 to 8 days later. On the other hand, acriflavine 1:1000 and euflavine 1:2000, like most other antiseptics, caused marked haemorrhage and necrosis. The effect *in vitro* of antiseptics on the respiration of brain tissue paralleled the above results (Manifold, 1941). The tolerance to compounds of proflavine type is clearly of high significance for brain surgery.

---

[*] For a thorough discussion of the principles of investigating chemotherapeutic antiseptics, see Garrod, L. P., *Lancet,* 1940, 1, 798, 845.

[†] 97,000 injections were given to about 6,000 patients. In some cases the dose was 0.2 or 0.3 g.

Leucocytes —In the usual opsonic experiments *in vitro* the presence of 1 : 500 to 1 : 1000 acriflavine or proflavine reduced the phagocytosis of a suspension of pyogenic staphylococci or streptococci to about 50% of the control. 5-aminoacridine behaved similarly, while the 2 : 7 derivative was somewhat more inhibitory (Albert *et al.*, 1938; Rubbo *et al.*, 1942). With mercuric chloride, iodine, or crystal violet 1 : 3500 to 1 : 7000 led to a similar reduction. After 2 hours' contact with 1 : 10,000 of the acridine drugs the phagocytic power of the leucocytes was little affected; according to Fleming longer contact with higher dilutions caused damage. The tests of Welch *et al.* (1942) indicated that acriflavine is not highly toxic for leucocytes. Albert *et al.* (1938) found that polymorphonuclear leucocytes after contact with 1 : 2000 proflavine or acriflavine for 90 minutes at 38° C. were still moderately motile, although stained bright yellow. But Abraham *et al.* (1941) recorded rapid high toxicity with proflavine. Bond (1917) had shown previously that, as measured by the iodophil reaction, leucocytes in granulation tissue were not seriously injured by contact with preparations containing 1 : 1000 acriflavine. Fleming concluded that even a momentary application of flavine 1 : 1000 to the leucocytes sufficed to destroy their bactericidal power. However, Gay and Morrison's observations on mixtures of acriflavine, virulent streptococci, specific antiserum (heated), and leucocytes showed that (*a*) low concentrations of the drug (1 : 128,000) produced sterilization, and (*b*) in its absence sterilization did not occur even when fresh normal serum (alexin) was added also. These extreme divergencies suggest that the workers' methods decide their results *in vitro*.

Tissue Culture.—According to Mueller, Hata, Wolff, and others, proflavine, acriflavine, and certain related compounds are distinguished by inhibiting streptococci in concentrations which are the same as or less than those damaging the tissues. On the other hand, Jacoby, Medawar, and Willmer (1941) found proflavine highly toxic for fibroblasts, macrophages, etc. Here again gross discrepancies appear. Since "culture" conditions represent a *tour de force* for animal cells rather than a normal state, comparisons reflecting adversely on the behaviour of cells in contrast to bacteria probably have little applicability *in vivo*. There are pathologists expert in tissue culture technique who consider that meanwhile this is too deeply involved in difficult problems of its own to be able to offer at the best more than a partial contribution to the solution of others.

Granulation Tissue.—I am indebted to Prof. D. F. Cappell and Dr. H. E. Hutchison (Pathology Department, St. Andrews University) for unpublished observations on absorption from treated wound surfaces. Flask-shaped wounds were made in the skin and subcutaneous tissues of rats by a special method; into these were introduced gauze and the solutions to be tested. Following the application of 1:1000 proflavine or acriflavine several times daily, the wound surface failed to develop impermeability to tetanus toxin, which occurs in untreated wounds usually within a week. Similarly, granulating wounds which had acquired impermeability became permeable again after treatment for some days. There was no difference in action between the two drugs under these conditions. On histological examination scantiness or alteration of the granulation tissue lining was a feature of the permeable wounds. But generalizations regarding permeability to toxins are not possible, because it was found that while newly inflicted wounds were permeable to the toxin of *Cl. oedematiens*, a state of impermeability set in after 18 hours; and this condition was not affected by the antiseptics. Further, in such experiments the anti-infective property of the drugs was intentionally excluded by using preformed toxins. Actually, these treated wounds were kept practically free from pyogenic infection, which occurred conspicuously in the untreated controls.

Chemotherapy of Recent Infections

Inoculation of recent wounds in guinea-pigs with virulent *B. diphtheriae* or in mice with virulent streptococci, or intraperitoneal inoculation of the latter, affords a most valuable test object. Failure to devitalize the organisms in each case quickly leads to death of the hosts. With *B. diphtheriae* brief washing of the infected wound with acriflavine solution (1 : 100 to 1 : 2500) 1 to 2 hours after inoculation regularly saved the animal's life. Washing with isotonic or 5% saline failed (13 acute deaths out of 14 animals), as usually also did treatment with carbolic acid 1:20 to 1:100 or bipp. Successful results with aminoacridine compounds have been repeatedly obtained in recent wounds of mice inoculated with streptococci. So, too, after intraperitoneal inoculation one intraperitoneal injection of the antiseptic after an hour's interval saved the life of 60% (Browning *et al.*, 1931). It is noteworthy that drug treatment of wounds infected with streptococci may succeed although excision fails to prevent general infection. An important fact is that a dose of the antiseptic sufficient to save the animal's life may, in the same concentration, take some hours to kill the streptococci *in vitro*. Thus the therapeutic action is clearly a co-operative effect—the defensive powers of the host disposing finally of organisms whose virulence has been reduced first by the drug. This reduction in virulence would explain clinically successful suture of treated wounds whose surfaces still harbour many organisms. These drugs also are effective in some infections with anaerobes. Recently McIntosh and Selbie (1942) inoculated mice intramuscularly with at least 100 times the fatal dose of *Cl. welchii* and then treated the site by injecting a drug. A well-tolerated dose of proflavine (0.5 mg.) was somewhat more efficacious in preventing death than 80 times as much sulphanilamide or sulphathiazole. Both classes of compounds acted when injected after an interval sufficient for some penetration of the organisms into the tissues, whereas zinc peroxide failed under the latter conditions. Hawking (1941) likewise found proflavine effective in guinea-pigs. Accordingly, *so far as the aminoacridine antiseptics are concerned, an unequivocal "yes" can be given to the question, "Is it possible, by the use of an antiseptic, to destroy an infection in a freshly inflicted wound before the bacteria have had time to grow out?"*

There is no evidence that subcutaneous and muscular tissues of animals behave so differently from those of the human that what holds true in principle of the former will fail in the latter. Successful prophylactic treatment of recent wounds in man with acriflavine or proflavine has often been recorded (Drummond and McNee; Colledge *et al.*, 1917). Two criticisms have been expressed. First, the results could be obtained equally by débridement alone. In view of the experimental work this objection falls. Secondly, "Is it justifiable for the surgical pessimist who distrusts his own cleanliness to use antiseptics in an attempt to cover up his own deficiencies?" This taunt ignores the fact that even surgical wounds are sites of diminished resistance and so are liable to infection—e.g., from the circulation. The development of spontaneous metastatic gas gangrene affords clear evidence of this route of infection (Learmonth, 1924). *Suitable antiseptics should be used prophylactically for all wounds*, simply because no one can foretell when, without their aid, even a minor trauma will result in major sepsis. Charteris's work with the oily preparation of proflavine oleate for avoidance of sepsis in radium therapy is another outstanding surgical application.

Treatment of Established Local Sepsis

Suppurating wounds as met with in man are not readily imitated in laboratory animals. Consequently one must examine well-controlled clinical evidence. For example, in Carslaw's case (No. 15), suffering from extensive bomb wounds of the face, great loss of tissue, and much suppuration in spite of treatment successively with iodoform gauze and moist eusol dressing, resort to flavine was followed in two days by great improvement in the general state, the inflammatory condition of the skin and soft tissues rapidly diminishing and large sloughs separating. "This case illustrates the rapidity with which flavine can clean up a foul lacerated wound which was not yielding to other methods of treatment." Graham recorded an unexceptionable experiment: three fairly severe burns of similar size affecting the hand and forearm—the whole depth of the epithelium being destroyed—were treated within an hour with acriflavine. After two days the dressing on the least severe burn was changed to wet boric acid lint, whereupon, unlike the others, it became painful and suppurated; return to acriflavine restored the good progress.

Carslaw's general method in war wounds was to secure an "open" wound with adequate drainage, any accessible foreign body being removed. Strips of gauze well soaked in 1:1000 flavine were lightly packed into the depths of the wound, which was then covered with folds of gauze similarly soaked, the whole being covered with waterproof. The folds of gauze were changed once or twice a day, but the packing was not as a rule removed until 48 hours after introduction. Bashford and his co-workers, while emphasizing defects of treatment with these antiseptics, nevertheless stated that "pus was generally very small in amount, and even where it had been present it usually rapidly diminished in quantity. . . . Any spreading infection that already existed generally subsided quickly. . . . The patient is apparently protected in some way from the absorption of toxic products"—surely no mean achievement. Recently in the Middle East Mitchell and Buttle have dealt with "wounded men who, either in spite of chemotherapy or more probably owing to its inadequate application, arrive at the base with their wounds in a grossly infected and purulent condition. In these cases the sulphanilamide drugs can do no more than prevent the spread of infection and they have comparatively little influence on the course of the local suppuration." The wounds were commonly deep or extensive, often involving bones or joints. The novel procedure of applying proflavine in dry powder form was adopted, it being spread over the whole surface of extensive wounds or cavities—never exceeding 2 g. in any case, and usually only about 0.5 g. or less, depending on the size of the lesion. It was never employed on more than two or three consecutive occasions, at intervals of 4 to 28 days. Most patients found the dressing painless. Improvement followed proflavine irrespective of the type of infective organism; and good results might be attained in cases which had failed to respond to one of the sulphonamide series. No other drug was as effective as proflavine in controlling or eliminating staphylococcal infection. Oily preparations of proflavine oleate, originally used by Berkeley and Bonney for dressing large raw surfaces, are also valuable—e.g., on septic sites preparatory to radium therapy (Charteris, 1937).

Influence on Healing

After 4 to 7 days' treatment a yellowish fibrinous membrane often covered the wounds (Carslaw; Drummond and McNee; Colledge *et al.*). At this stage the flavines had fulfilled their therapeutic purpose in preventing or overcoming sepsis, and a change of treatment was indicated—e.g., on using eusol the pellicle disappeared, while granulation and growth of epithelium proceeded (Carslaw). Bashford and his collaborators, working at the Surgical Observation Hut organized by Surg. Gen. Sir George Makins, picked for trial with the flavines 50 patients of whom they said "almost all had been treated previously at the front by the Carrel-Dakin method within 24 hours of being wounded, and, in the majority of instances, very efficiently." The reason for this selection of cases already effectively treated by another method is hard to explain. However, despite the beneficial effects mentioned above, they chiefly dwelt on the delay in all the processes of repair; later, this work was quoted extensively by Makins (1922) in the *Official History of the War.* Pilcher and Hull, writing at the time from their own experience of over 5,000 cases in military hospitals, made the following comment: "For ease of preparation and application, rapidity when dealing with large numbers of cases, complete absence of surgical fidget, early cleaning of the wounds, and abatement of constitutional reaction to absorption, flavine is an admirable application under all circumstances, but especially where surgeons are few, time is short, and wounds are many." The factors in treatment which may retard healing have not yet been fully defined. Bennett did not experience it in over 600 cases. In tissues from this series Blacklock found mitoses of various cell types at levels of 1/50 to 1/5 mm. below the actual growing surface. The margin between the optimum and too high a concentration of the drug due to frequent renewal or evaporation may be narrow. A modified treatment consisting of less frequent applications and weaker solutions—1 : 5000 or under—in later stages has not been widely enough tried. Mitchell and Buttle attributed possible interference with healing to proflavine powder only once in 80 cases.

Conclusions

1. Aminoacridine ("flavine") compounds were introduced as surface chemotherapeutic agents for wounds because they combined outstanding antiseptic properties with relatively low toxicity, as demonstrated by simple methods *in vivo* and *in vitro*. Later tests *in vitro* have yielded discordant results *inter se*, which throw doubt on their value as a practical means of selecting drugs for such purposes.

2. Proflavine is the precursor of acriflavine, and so cheaper. Also, while equally antiseptic, proflavine is the less toxic generally, and especially is very little harmful to brain tissue. Recently introduced members of the series may prove even more suitable for therapy.

3. It has been shown under experimental conditions that the flavines when applied to the tissues at the site of inoculation are highly effective in preventing the development of infection with various organisms, including streptococci and certain gas-gangrene anaerobes.

4. Also, there is good clinical evidence that they can control established suppuration in wounds. This may occur where drugs of the sulphonamide group have failed.

5. Retardation of granulation and healing tends to follow continued use of the flavines, so that it may be advantageous to resort to other treatment later. But the point important practically is the capacity of the flavines to prevent or control infection. This so-called "pickling" or "cold-storage" effect has enabled wounded men to be transported without re-dressing, in the fair likelihood that their wounds would remain *in statu quo ante* as regards infection.

HERNIA THROUGH THE FORAMEN OF WINSLOW, EMERGING THROUGH THE GASTRO-HEPATIC OMENTUM

BY

Brigadier HAROLD EDWARDS, M.S., F.R.C.S.
Consulting Surgeon to Southern Command

AND

Major W. STEWART, M.D.
Pathologist, R.A.M.C.

Hernia through the foramen of Winslow into the lesser sac is one of the more uncommon abdominal surgical conditions, and the re-entry of the herniated bowel back into the general abdominal cavity through the lesser omentum appears to be still more rare. The transverse colon probably acts as a barrier to herniation. The anterior and posterior boundaries of the foramen during life are in direct contact, and the opening is a slit-like passage (Cunningham's *Anatomy*, 7th ed., p. 576).

Moynihan and Dobson (1906) state that herniation through this foramen requires one of the following conditions: (*a*) a common mesentery of the whole intestine; (*b*) absence of secondary fusion of the ascending portion of the colon; (*c*) an abnormally large foramen; (*d*) abnormal length of mesentery and consequently marked mobility of the intestine. These writers call attention to the unlikelihood of a hernia into the lesser sac because of the normal anatomical conditions at the potential "foramen."

Since 1910 29 cases of internal herniae have been seen at the Mayo Clinic; of these one occurred into the lesser sac (Mayo *et al.*, 1940). Silverstone (1939) describes a case. He states that it is unlikely to occur in a normal abdomen. The condition is more common in men than in women—28 of the former to 11 of the latter. In his view there are two clinical groups: acute, with intestinal obstruction; chronic, with digestive symptoms for years. The small intestine is twice as often involved as the large bowel, and the site of strangulation appears to be at the margins of the foramen, which in Silverstone's case was enlarged and admitted the index and middle fingers at the time of operation. It was found possible to reduce the hernia, but the patient died a few hours later. In Mitchell's (1938) case the caecum, appendix, and 9 in. of the lower ileum had passed into the lesser sac in a male infant of 15 months. After reduction of the bowel at operation the foramen admitted the forefinger with difficulty. In Barrington-Ward's (1937) series, in the case reported by Haw the involved portion of bowel (lower part of ileum, caecum, and appendix) could not even be reduced at the necropsy till the gastro-hepatic omentum had been divided.

Cases in the Literature

Four cases occur in the literature which seem to resemble the one described below. The first is that reported by Treves (1888), in which a coil of colon had entered the foramen and forced its way through the lesser omentum so that the vermiform appendix was actually lying on the anterior aspect of the lesser curvature of the stomach, close to the oesophagus. In Copenhaver's (1923) case the caecum and ascending colon had a long free mesentery: after entering the lesser sac, rupture had occurred through the anterior leaf of the lesser omentum and they were hanging down in front of the stomach. It was found impossible to reduce the hernia, but later a fatal volvulus developed. In that of Rock Carling and Smith (1925) the patient had been perfectly well the previous day. The following morning he felt rather sick, and towards night there was severe pain. This pain was extreme, and sitting up in bed tended to give some slight relief. He was admitted to hospital on the third day, when a leaking gastric ulcer was diagnosed. The pulse was 68 and the temperature 97° F. There was some tenderness in the upper abdomen, but this was not pronounced. At operation a loop of small bowel was seen to have herniated through the foramen of Winslow and then re-entered the general abdominal cavity through a gap in the gastro-hepatic omentum. The gut was reduced and the rent in the omentum repaired. The bowel involved was the middle 20 in. of the ileum. The mesentery was unduly long. Post-operative recovery was complete. In Schmilinsky's (1919) case a similar condition was found, and this patient was operated on successfully. Some similar features were also observed by Blandin (1834), but in this case the gut after entering the lesser sac had left it and then re-entered the lesser sac through the transverse mesocolon.

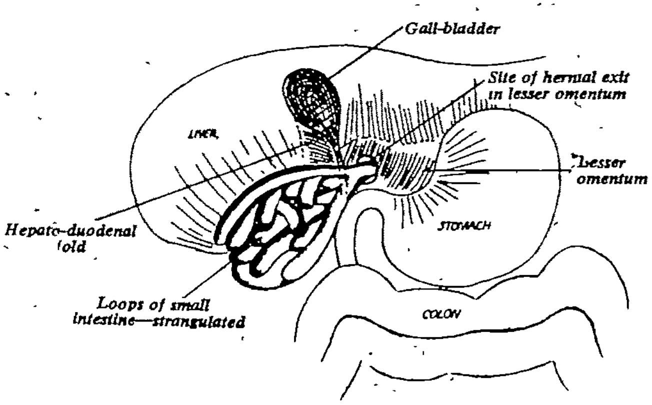
This type of hernia is accompanied by a considerable mortality. In Rendle Short's (1924) series of retroperitoneal herniae 24 were through the foramen of Winslow; 6 men were not operated on, but died of strangulation; 11 died in spite of operation; and 7 survived. Souttar (1940) states that it is fortunate that internal herniae are rare, since if strangulation does occur the condition is almost invariably fatal.

A fifth case of this type of herniation is now placed on record.

History of the Present Case

A young guardsman aged 26 was admitted to a Service hospital with a history of dull, aching, non-radiating pain in the upper abdomen of some eight hours' duration. About two hours after the onset he had vomited twice; this vomit consisted of food, and no blood had been seen. No constipation was present, his bowels having been opened the previous day. A few similar attacks had occurred in the past. On admission the pulse was 64, temperature 98° F., and respirations 21; the blood pressure was 120/96. Abdominal examination revealed some tenderness and resistance in the upper part, but the respiratory excursions were maintained. Liver dullness appeared normal. The other systems showed no abnormality. A few hours later his general condition worsened: generalized abdominal rigidity and tenderness set in; the liver dullness disappeared; the pulse, after falling, increased considerably; and the systolic blood pressure dropped to 90. A transfusion with plasma was given, and laparotomy was performed under local anaesthesia followed by oxygen and ether. The abdomen contained much blood-stained fluid and, in the right upper quadrant below the liver, a large mass of engorged haemorrhagic small bowel. The bowel was seen to pass through the foramen of Winslow, which easily admitted one finger. The patient collapsed on the operating table, and attempts at resuscitation failed.

At the post-mortem examination the abdomen was found extremely distended. The heart was normal apart from some terminal dilatation, the mitral valve taking three fingers and the tricuspid four; the aortic and pulmonary valves were also normal. The lungs showed some congestion. An increased amount of thymus tissue was present. The abdominal cavity contained much blood-stained fluid, and lying under the liver were loops of strangulated small intestine which had passed through the foramen of Winslow and then re-entered the general abdominal cavity through an opening in the lesser omentum (see Fig.). The site of strangulation was seen to be at the opening in the omentum and not at the margins of the foramen. The bowel involved in the strangulation was the lower ileum except the terminal 12 in., and it measured 6 ft. The proximal portion of the bowel was much distended and congested. The stomach was ballooned out, and contained 1¼ pints of fluid and undigested food. Liver, spleen, kidney, suprarenals, urinary bladder, and prostate showed nothing of note, and the brain was normal.



Gall-bladder
Site of hernial exit in lesser omentum
LIVER
Lesser omentum
STOMACH
Hepato-duodenal fold
Loops of small intestine—strangulated
COLON

The strangulated portion of bowel could only be reduced with difficulty, but it was not necessary to divide the lesser omentum. After reduction the mesentery was seen to be unduly long. The foramen of Winslow was dilated, taking two fingers easily; no rounded anterior margin was present, but there was a dense band of fibrous tissue stretching between the gall-bladder and the first part of the duodenum; this appeared to blend with the lesser omentum (see Fig.). The bile duct, portal vein, and hepatic artery were present in the lesser omentum, occupying a position midway between the free margin of the fibrous band and the right lateral wall of the artificial opening in the lesser omentum. The breadth of the band of fibrous tissue from the cystic duct to the free margin measured 4 cm. The further opening into the lesser sac was immediately beneath the opening in the lesser omentum. The artificial opening in the omentum measured 1.5 cm. in length by 1.25 cm. in breadth. No fluid, blood adhesion, or other abnormality was seen in the lesser sac.

Discussion

The slow pulse rate was rather unexpected. The condition of the patient on admission was undoubtedly serious, and yet the rate was only 64, with a further drop later. It did not increase till a few hours before death. A slow pulse rate was also present in Rendle Short's case. This degree of bradycardia may clinically be misleading, and is possibly due to the close association between the nerve supply of the site of the artificial opening in the lesser omentum and the innervation of the heart. The site of the strangulated coils in the present case varies slightly from that of the cases described by others. In our case no coils were overlying the stomach, the amount of intestine was greater, and there was the extreme gastric distension which would push the strangulated bowel towards the right lobe of the liver.

The herniation itself presents interesting features which merit consideration—the opening in the lesser omentum and the accessory band of tissue between the gall-bladder and the duodenum. Prof. Blair has given us his opinion of these. The aperture in the lesser omentum is not likely to be congenital; it is more likely to be "acquired." He has not seen such a congenital defect, nor does he know of any developmental reason why it should occur. In the dissecting-room the lesser omentum is of so delicate a nature that one can imagine it would be readily torn by any hernia spreading within that part of the lesser sac. Indeed, in the anatomy room the lesser omentum is often torn through at the first attempt to pull down the stomach a little in order to explore the region between it and the liver. The band of tissue between the gall-bladder and the duodenum was an unusually well-developed example of the hepato-duodenal fold, which is not infrequently present to a lesser degree and represents a thinned-out part of the lower free border of the ventral mesentery of the fore-gut, which amounts to a prolongation, rather further to the right than usual, of the lesser omentum. The presence of this cystico-duodenal fold of membrane would produce a funnel-shaped approach to the foramen of Winslow and considerably assist an unusually mobile loop of bowel towards the foramen and into the lesser sac. This appears to us a considered and well-founded explanation of the appearances found post mortem.

The appearance of the foramen at the necropsy led one to suspect that perhaps a loop of bowel had been herniated for some time. Such a condition has been described by Schwalbe (1904) in which strangulation did not occur.

In comparison with herniae into the lesser sac, herniation into paraduodenal fossae is relatively common and the literature on such is now quite voluminous.

Summary

A fifth case of this unusual type of herniation is now described. Three abnormal features were present in the abdominal cavity: (1) a well-developed hepato-duodenal fold which had produced a funnel-shaped approach to the lesser sac; (2) a dilated foramen of Winslow; (3) an undue length of mesentery of the small bowel.

We consider that the first and third factors, in association with the normal peristaltic movements, could produce a dilatation of the foramen and so give rise more readily to the herniation which had ruptured through the lesser omentum.

It is a pleasure to us to express our gratitude to Prof. D. Blair, Regius Professor of Anatomy, University of Glasgow, for his co-operation and help, and to Col. M. J. Williamson, *M.C.*, late R.A.M.C., for permission to record this case.

Hospitals in the Midlands (especially those in Birmingham), children in Yugoslavia and Greece, and youth organizations are among the beneficiaries under the will of Sir Charles Hyde. He has left £10,000 for the benefit of children in Yugoslavia and Greece, and £2,000 each to the Royal Cripples Hospital, Birmingham, and the Coventry and Warwickshire Hospital. A number of hospitals in Birmingham and Worcester will receive £1,000 each, and £3,000 is for the Ophthalmic Hospital at Jerusalem. The Senate of Birmingham University is to receive £20,000 for enlargement of the students' union, and Clifton College a similar sum for scholarships. The residue of the estate is to be divided equally between the University of Birmingham, Queen Elizabeth Hospital, Birmingham, King George's Jubilee Trust, and Dr. Barnardo's Homes.

USE OF METHEDRINE, A NEW BLOOD-PRESSURE-RAISING DRUG, IN SURGICAL OPERATIONS

REPORT OF A CLINICAL STUDY

BY

HAROLD DODD, Ch.M., F.R.C.S.

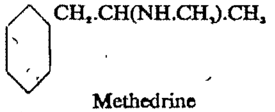
Surgeon to King George Hospital, Ilford, and to the Royal Hospital, Richmond; Assistant Surgeon to the London Homoeopathic Hospital

AND

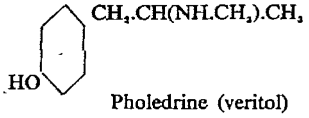
FREDERICK PRESCOTT, M.Sc., Ph.D., A.I.C., M.R.C.S.

The Wellcome Research Institution

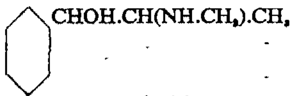
During the last ten years one of us (H. D.) has studied the use of pressor agents to counteract the serious falls of blood pressure unaccompanied by severe reduction of blood volume that often occur during major operations. The pressor effects of adrenaline, ephedrine, pholedrine (veritol), and neosynephrin have been recorded, but none of these drugs is effective for more than 30 to 45 minutes, and repeated injections are often necessary. S-methylisothiourea has recently been reported on (Smirk and McGeorge, 1942), but has the disadvantage that it must be injected intravenously. In a search for an effective pressor agent with a sustained action that could be administered by any route under average clinical conditions we examined methedrine.* This is a sympathomimetic drug, and was chosen because of its relation to pholedrine.



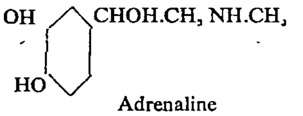
Methedrine



Pholedrine (veritol)



Ephedrine



Adrenaline

Conditions of Use

Blood pressures and pulse rates were recorded every three to five minutes in 130 operations, many of them major, and in 54 of these the systolic pressure or the pulse pressure dropped sufficiently for the patient to need a pressor agent. Methedrine was used solely in these cases—no other agents or stimulants were given—and was administered when the systolic pressure fell to and remained at 80 mm. or less, or when the pulse pressure was 10 mm. or less; 20 minutes was allowed first for natural recovery. According to Hewer (1943) the systolic pressure during operation should not be allowed to drop below 80 mm. for more than 20 minutes. Methedrine was administered only when the surgeon, anaesthetist, and recorder agreed that the patient's condition required it. If the systolic pressure fell to 60 mm. or less during the operation methedrine was usually given after a few minutes, as such low levels were considered inadequate for the vital processes to be sustained, and if prolonged might lead to surgical shock (McMichael, 1942). The low blood pressure often resulting from spinal anaesthesia is regarded by some as a type of secondary shock (Schuberth, 1936). We found that spontaneous recovery from blood pressures as low as 60 mm. did not occur within 1½ hours.

We wish to point out the necessity for the routine determination of blood pressures in all major operations, irrespective of risk, to anticipate and prevent surgical shock. The behaviour of the patient cannot be predicted. We have seen elderly poor-risk patients survive a splenectomy or a complicated gastric resection with hardly any fall in blood pressure, yet young and moderately fit patients have shown a pronounced fall in comparatively minor operations.

---

* "Methedrine" is the Burroughs Wellcome and Co. trade mark for N-methylamphetamine, the hydrochloride of which was used in this study. The Continental name is pervitin.

Anaesthetics Used

The anaesthetics employed included (*a*) *spinal,* 1 in 1,500 or 1 in 2,000 nupercaine, alone or supplemented by general anaesthetics; local procaine or amethocaine, or pentothal; (*b*) *general anaesthetics* such as gas and oxygen, gas–oxygen–ether, open ether, and trichlorethylene; (*c*) *local anaesthetics* such as procaine or amethocaine, alone or supplemented with the general anaesthetics mentioned above or with pentothal; (*d*) *intravenous anaesthesia* with pentothal, either alone or with a general anaesthetic.

A fall in blood pressure usually, although not always, occurs after giving a spinal anaesthetic. Pressor agents are often given prophylactically to prevent this, but we preferred to correct the fall if and when it occurred, after allowing 20 minutes for spontaneous recovery, although this does not normally result until sensation is returning (Koster, 1942). If the spinal anaesthetic does not bring about a fall in blood pressure and a pressor agent is administered, the resulting rise in blood pressure causes increased haemorrhage from the operation wound.

Administration and Dosage

Methedrine is effective subcutaneously, intramuscularly, and intravenously. In cases with a profound fall in blood pressure the best results were obtained with a combination of the intravenous and intramuscular routes, the intravenous injection producing an almost instant rise, while the intramuscular injection acted more slowly (in 2 to 10 minutes), but maintained the blood pressure for a considerable time after the intravenous dose had ceased to act. Patients with a low blood pressure often had collapsed veins. In such cases we did not lose time trying to enter them, but gave the methedrine intramuscularly.

A total of 68 injections was given intramuscularly and 17 intravenously; of the latter 14 were given simultaneously with intramuscular injections.

Single Doses.—The dose for a single intramuscular injection of methedrine varied from 15 to 30 mg., and for a single intravenous injection from 10 to 20 mg. The dose depended upon the patient's condition. In 44 out of 54 cases studied—i.e., 81%—a single injection was sufficient to restore the blood pressure to normal limits. In *minor operations* (e.g., for hernia or varicose veins), if the systolic pressure dropped to 90 mm. and the pulse pressure to 15 to 10 mm. or less, an intramuscular injection of from 15 to 20 mg. was given; this was increased to 25 mg. if the systolic pressure fell to 80 mm. or below. Intravenous injection is not necessary in these cases. In *major operations* in which the blood pressure fell below 80 mm. the dosage of methedrine was from 25 to 30 mg., given either intramuscularly in a single dose or as a combined injection of from 10 to 15 mg. intravenously and 15 to 20 mg. intramuscularly. When the systolic blood pressure fell to 60 to 40 mm. or less, from 15 to 20 mg. of methedrine was given intramuscularly and 15 to 20 mg. intravenously. Only two patients received the maximum single dose of 20 mg. i.m. plus 20 mg. i.v. Patients with a low blood pressure need larger doses. We would emphasize that each case must be critically evaluated in the light of the patient's condition, age, and physique as well as the blood pressure and respiration.

Multiple Injections.—In 10 of our cases more than one injection was given, although subsequent experience revealed that the first dose was too low in 4 of these, leaving 6 who really required more than one injection. At least 20 minutes was allowed for the first injection to exert its full effect before giving another. Seven patients required two injections to restore the blood pressure to normal, although in 4 of these the initial dosage was experimental and too cautious, leaving 3 who actually needed a second injection. In 3 cases three injections were necessary to raise the blood pressure to normal levels; one of these was a mastectomy, in which three small doses were given deliberately to minimize the risk of haemorrhage from the large traumatized area.

Although the maximum single dose of methedrine given was a combined injection of 20 mg. intramuscularly and 20 mg. intravenously (i.e., a total of 40 mg.), the maximum total dosage received by any one patient was 75 mg., given in three injections over a period of 1¼ hours. Other patients received total doses of 70, 65, 55, and 50 mg. respectively. No untoward effects were observed in these patients, and with one exception, in which post-operative vomiting occurred, they all made an uneventful recovery.

Time taken for Methedrine to Act

Intravenously.—After an intravenous injection the blood pressure began to rise almost at once—certainly within a minute. The time taken for the blood pressure to reach its maximum value depended on the dose and varied considerably from individual to individual. The shortest time was 2 minutes and the longest 10 minutes in the cases studied, with an average of 5½ minutes.

Intramuscularly.—An intramuscular dose of 15 to 30 mg. of methedrine produced a measurable rise of blood pressure in from 2 to 10 minutes (one case took 15 minutes), with an average of 4 minutes. The maximum rise in blood pressure after an intramuscular injection was reached in from 4 to 38 minutes, with an average of 18 minutes. In the 10 cases studied second intramuscular doses reached their maximum effect in from 5 to 20 minutes, with an average of 15 minutes.

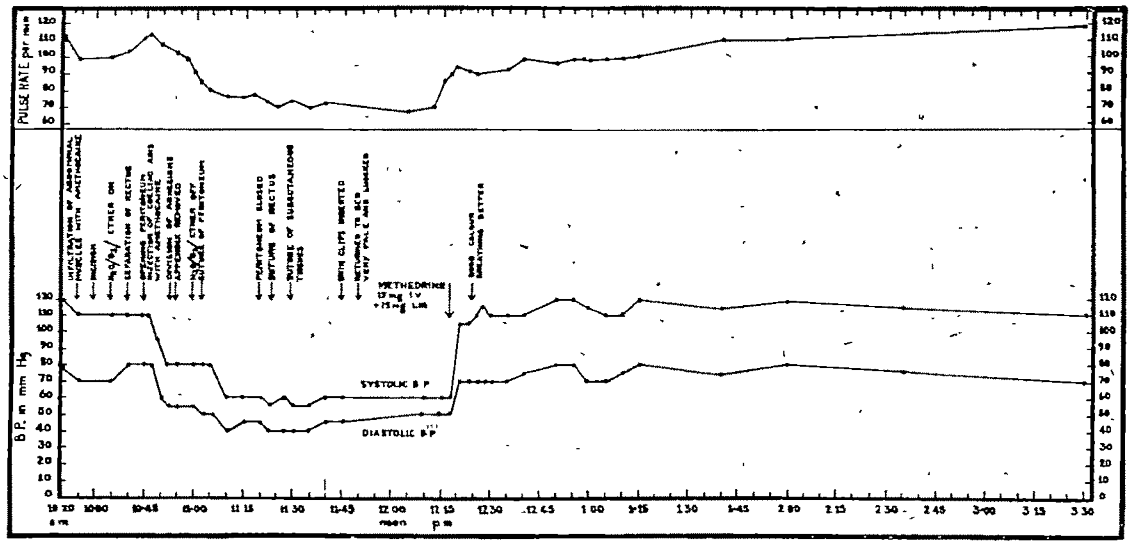


FIG. 1.—Effect of combined intramuscular and intravenous injection of methedrine on blood pressure and pulse rate after a laparotomy in which the blood pressure fell to 60 mm. Hg and showed no sign of natural recovery.

Duration of Action of Methedrine

The duration of action of an intravenous dose of methedrine is variable. It may last for half an hour or for several hours. A carefully calculated intramuscular dose or a combined intramuscular-intravenous dose produces an effect which lasts for many hours. In 44 out of the 54 cases a single intramuscular injection or combined intramuscular-intravenous injection permanently restored the systolic pressure to its pre-operative level or to within 90% of it. This pressure was sustained, with small variations, throughout the operation and for recorded periods of from half an hour to over 48 hours afterwards. Nine cases required more than one injection to raise the blood-pressure to normal values; in all of these the effect was sustained throughout the operation and for several hours afterwards. In only 1 of the 54 cases did the methedrine fail to restore and maintain the systolic blood pressure above 100 mm.

Evaluation of Pressor Effect of Methedrine

Systolic Pressure.—We have been impressed by the effective and sustained pressor action of methedrine. Omitting the first case, in which the dosage and mode of administration were largely a question of trial and error, only one case failed to respond to the drug. In 97% of the cases the blood pressure was restored to normal levels in a period varying from 2 to 18 minutes. The general effect of a carefully calculated injection, given by the combined intravenous-intramuscular route, on a patient with a systolic blood pressure that has fallen from normal levels to between 80 and 40 mm. is as follows. A measurable rise in systolic pressure occurs in 1 minute, reaches a maximum in a period varying from 5 to 15 minutes, and is sustained over a period of several hours after the operation (see Fig. 1). There is no precipitate rise and fall such as occurs with pressor agents like adrenaline and ephedrine (Dodd, 1940). The blood-pressure curve is of a plateau and not a peak type. After an intramuscular injection (Fig. 2) the rise in blood pressure is not so rapid, but the maximum pressure is of the same order as after an intravenous injection, and the action is usually more prolonged.

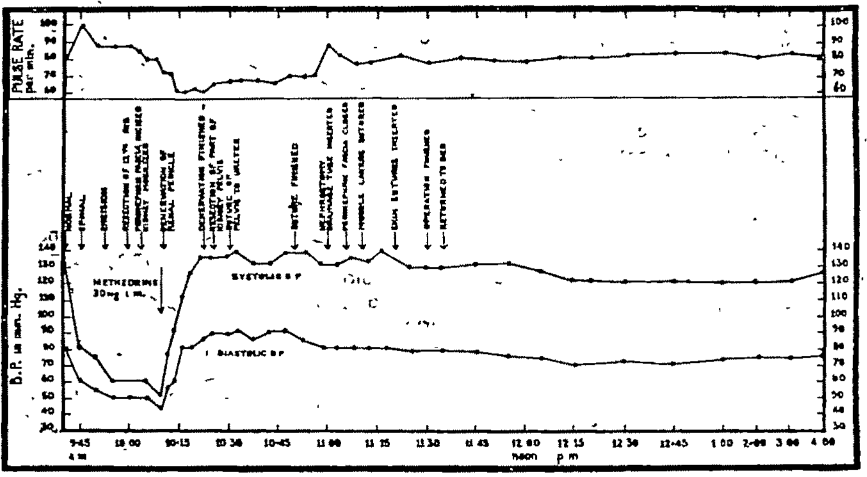

FIG. 2.—Effect of intramuscular injection of methedrine on blood pressure and pulse rate during operation for renal sympathectomy, pyeloplasty, and nephrostomy.

The maximum systolic pressure after the injection rarely rises much above the pre-operative value unless an overdose is given. In only 3 of our cases did it rise more than 30 mm. above this value. The blood pressure quickly settled down to the pre-operative level or within 90% of it. The average systolic blood pressure of our 54 patients just before operation was 137 mm. The average systolic pressure of these patients when the methedrine was given was 66 mm., which rose to an average maximum of 135 mm. in an average time of 18 minutes. The average figure to which it finally settled, measured at periods of from half an hour to 48 hours after operation, was 124 mm. This corresponds to a permanent rise to an average of 91% of the pre-operative level. Repeated observation of the blood pressure over periods of several hours after operation showed that this level was maintained.

Diastolic Pressure.—The average diastolic pressure just before administering methedrine was 52 mm.; after the drug was given it rose and was sustained at an average value of 84 mm. The corresponding figures for the average pulse pressures were 14 and 40 mm. respectively.

Pulse Rate.—The effect of the methedrine on the pulse rate was variable. Generally there was an increase of 15 beats to the minute on the average, although in 6 patients there was a fall of an average of 12 beats per minute. In 3 cases the pulse rate was unaffected. After administering methedrine to collapsed and pulseless patients the pulse soon became full and bounding.

Respiration.—This was not systematically recorded, but an increase in the rate and depth of respiration was noted in many patients.

Repeated Doses.—Repeated injections were effective, but the best response was obtained by a carefully selected adequate dose given in one injection rather than in divided doses. Small repeated doses are unsatisfactory.

Reactions

Apart from extrasystoles no abnormal clinical findings were observed in patients who were given methedrine in the correct dosage. Extrasystoles were noted in 3 patients; these were also observed under anaesthesia when methedrine had not been given. In normal persons methedrine acts as a cortical stimulant (Golla *et al.*, 1940), but this effect was not observed in our patients, being presumably annulled by the premedication, the anaesthetic, and the post-operative morphine that they received. Three patients out of 54 became excited or delirious post-operatively, but we consider this incidence to be within normal.

When one of us received 70 mg. of methedrine intramuscularly in divided doses over five hours the systolic blood pressure rose from 130 to 180 mm., and vomiting, cortical stimulation, persistent tachycardia, and severe palpitations were experienced. The acute symptoms lasted 24 hours and the tachycardia and palpitations for several days. We would therefore suggest caution in giving total doses of more than, say, 60 mg. of methedrine, although this dose appears to be well tolerated by patients with a low blood pressure. Pressor agents are potent drugs and must always be used with caution; they should never be given without reading the blood pressure before each injection. Overdosage may be disastrous in a patient with cardiovascular disease or hyperthyroidism.

Electrocardiograms

These were taken in 3 patients, two of whom received the maximum single dose of 40 mg. No significant permanent changes were observed. In one case we observed a shortened RST segment in lead II, iso-electric waves in lead I, and upward displacement of the ST segment in leads II and III. These changes were transient, and we attach no significance to them. An E.C.G. of one of us taken 24 hours after the administration of 70 mg. of methedrine was normal. It must be remembered that anaesthetics, surgical trauma, and many drugs used in emergencies produce temporary changes in the E.C.G. (Kurtz *et al.*, 1936; Brechling and Hansen, 1939; Graybiel and White, 1941; Hartwell *et al.*, 1942).

Comparison with other Pressor Agents

One of us (Dodd, 1939, 1940, 1942) has had the opportunity of comparing clinically the pressor effects of methedrine with those of adrenaline, ephedrine, and pholedrine (veritol). We consider that the pressor effect of methedrine is superior to that of these drugs because: (*a*) it does not produce a precipitate rise and fall of blood pressure; (*b*) the blood pressure is restored to and maintained at its pre-operative level or within 90% of it for several hours, not for 30 to 45 minutes; (*c*) one injection is usually enough.

We have not had the opportunity of testing neosynephrin and paredrine, two sympathomimetic pressor drugs recently used in America during operations under spinal anaesthesia. The duration of action of a single dose of neosynephrin is only half to three-quarters of an hour, and several injections (from two to six) are sometimes necessary to raise and maintain the blood pressure during the course of operations under spinal anaesthesia (Johnson, 1937; Lorhan and Oliverio, 1938; Bittrich, 1939; Brunner and de Takats, 1939; Silvers and Leonard, 1940; Lorhan and Lalich, 1940). The initial rise in blood pressure due to the drug may also be excessive, and the bradycardia which it causes has resulted in partial heart-block (Brunner and de Takats, 1939). Paredrine may also produce an excessive rise in blood pressure—e.g., to 250 mm. systolic (Loman *et al.*, 1939; Altschule and Gilman, 1939).

It would thus seem that methedrine is the most valuable of the drugs so far tested for counteracting the serious falls in blood pressure that often occur in surgical operations. The 54 cases of the series under review are summarized in the table below.

Summary of Cases showing Effect of Methedrine on Blood Pressure

No.	Operation	Dose in mg.	Pre-operative B P.	Lowes B.P	Max. B P after Methedrine	Final B P. in Ward

We have not had the opportunity of using methedrine in cases of traumatic shock, but we think that the outstanding properties of the drug make it worthy of trial in such cases, particularly in those which fail to respond to measures designed to increase the blood volume.

Summary

Out of 130 observed operations 54 patients were found suffering from an unduly low systolic or pulse pressure and some degree of impending surgical shock. The capacity of methedrine to meet the needs of these patients has been studied under average general hospital operating conditions. Anaesthetics included all those in common use. Under these conditions methedrine has been found to be an effective blood-pressure-raising drug with a prolonged action.

The effective dose is from 15 to 30 mg. intramuscularly, or 10 to 20 mg. intravenously plus a depot dose of 10 to 20 g. intramuscularly.

In 97% of the cases the systolic pressure was restored to normal levels in a period varying from 2 to 18 minutes. The systolic pressure was raised from an average of 66 mm. to an average maximum of 135 mm., and settled to an average minimum of 124 mm. This last figure corresponds to 91% of the average pre-operative value (137 mm.). There is no abnormally high rise if the dose is carefully calculated. One injection was adequate in 81% of patients; repeated injections were given in 17%; 1 case (2%) did not respond.

The blood pressure was maintained throughout operation and for several hours after.

Reasons are given for considering methedrine to be superior to adrenaline, ephedrine, pholedrine, neosynephrin, and paredrine for counteracting serious falls of blood pressure in surgical operations.

We wish to thank Drs. M. Griffiths, Hunt, Fraser Simpson, and Barnes for their help and co-operation in this study.

TETRACHLORETHANE POISONING

BY

GILBERT FORBES, B.Sc., M.B., Ch.B., F.R.F.P.S., F.R.C.S.Ed.

Lecturer in Forensic Medicine at the University of Sheffield; Police Surgeon to the City of Sheffield

Tetrachlorethane ($C_2H_2Cl_4$) is a colourless mobile liquid with an odour resembling that of carbon tetrachloride and chloroform. It is non-inflammable, and the commercial product has a boiling-point varying from 140 to 150° C. and a specific gravity of from 1600 to 1602 (Browning, 1937). It is a solvent for cellulose acetate and nitrate, bitumen, waxes, resins, pitch, tar, sulphur, rubber, and oils.

This substance is sold under various trade names, such as "westron," "alanol," "emaillet" (Browning, 1937), and "cellon" (Willcox, 1915). It is issued to the Army as "silk-cleansing fluid" for the purpose of cleaning the silk of duplicators (Hepple, 1927; Elliott, 1933). Corry's white fly fumigant, which is stocked by most nurserymen and seedsmen for sale in small quantities, is composed of nearly pure tetrachlorethane. Its sale is not controlled by the Dangerous Drugs Acts, 1920-32, and though not commonly stocked by retail chemists it may be bought from some at the price of 2s. a pint.

Commercial Uses

During the early stages of the war of 1914-18 tetrachlorethane was extensively used, both in this country and on the Continent, as a constituent of the solution employed to treat aeroplane fabric so as to render the wings of aircraft impervious to air and moisture. In July, 1916, its use for this purpose was prohibited, as by that time 70 cases of jaundice with 12 deaths had occurred as a direct result of inhalation of the vapour (Willcox, 1915), and a substitute of a non-toxic nature was provided as a solvent for cellulose acetate. Tetrachlorethane, however, has a very wide field of application in other industries, on account of both its high solvent power and its properties as an insecticide. The following list of its commercial uses is given in the report of the Industrial Health Research Board (Browning, 1937):

1. As a dry-cleaning agent.
2. As a lacquer solvent in the manufacture of straw hats.
3. In the film industry as a celluloid solvent.
4. In the artificial silk industry, particularly in the "lustron" process.
5. In Germany and France, principally as a solvent for a mixture of acetyl-cellulose and "essence d'orient" in the manufacture of artificial pearls.
6. As a cement in the manufacture of shoes.
7. As a parasiticide, especially as a hair wash for dogs, perfumed substances being added.
8. In the estimation of the water content of tobacco and many drugs.
9. In the manufacture of tube cements, adhesives, and floor waxes.
10. As a constituent of the adhesive used in the manufacture of gas masks.
11. As a component in the contents of foam fire extinguishers.
12. For the impregnation of furs and skins.
13. In the manufacture of safety glass.
14. In the rubber industry to some slight extent.

Absorption, Distribution, and Excretion

Tetrachlorethane is mainly absorbed through the lungs, but, as shown by Schwander (1936), enough may be absorbed through the skin to produce complete narcosis. It can of course be absorbed from the alimentary canal. It is largely excreted through the lungs, but this takes place slowly, as shown by animal experiments. Part of the absorbed material is excreted in the urine (von Oettingen, 1937).

Toxicity

Tetrachlorethane is generally considered the most toxic of the chlorinated hydrocarbons (Hamilton, 1934; Browning, 1937), whether of the saturated or of the unsaturated series, not only exerting a narcotic effect but producing profound organic damage, especially atrophy of the liver. As a narcotic poison it works more slowly than chloroform, but its effects are more lasting. As it is not volatile, acute narcosis from the fumes of this substance is never very bad; but, on the other hand, chronic poisoning is notoriously severe, and affects a fairly high proportion of those exposed. Hamilton quotes Lehman to the effect that, based on experimental evidence, tetrachlorethane is four times as toxic as chloroform. Veley—according to Willcox—found that it is 2.8 times as toxic as chloroform. Von Oettingen cites Müller to the effect that tetrachlorethane is 3.5 times more toxic to mice than chloroform. Lehman and Schmidt-Kehl (quoted by von Oettingen, 1937) found that, in man, concentrations of 0.02 mg. per litre may be detected by odour, 0.09 mg. per litre may be tolerated without effect for 10 minutes, but that inhalation of 1 mg. per litre for 30 minutes or 2.3 mg. per litre for 10 minutes will cause irritation of the mucous membranes, pressure in the head, vertigo, and fatigue. According to their findings, 45 to 46% of the inhaled material is absorbed through the lungs.

Tetrachlorethane Poisoning in Man

Poisoning by this substance may be either acute or chronic. The former is rare, the latter more common.

Acute Poisoning

So far as I have been able to discover, only two cases of poisoning following ingestion of this solvent have been recorded. The reason for this is not far to seek, as tetrachlorethane is most unpalatable and has a distinctly disagreeable odour.

The first case was reported by Hepple in 1927, the second by Elliott in 1933. The two cases are very similar. In both the victims were members of H.M. Forces, and they both drank "silk-cleansing fluid." They became unconscious shortly after ingestion of the substance, with cyanosis and loss of corneal reflexes. They both died, one eight hours and the other twelve hours after taking the drug, in spite of every possible type of resuscitation treatment. Post-mortem examinations showed hyperaemia of the gastric mucosa, and in Hepple's case small areas of superficial erosion at the cardiac and pyloric ends of the viscus. Congestion of the kidneys and acute congestion of the lungs were present. No lesions of the liver were found apart from cloudy swelling and congestion in the case reported by Hepple. From the accounts it is quite clear that death took place in both cases from central respiratory paralysis. In Hepple's case the stomach was washed out, but in spite of this an analysis of its contents recovered at the necropsy yielded 12 c.cm. of a fluid with a specific gravity of 1600 and a boiling-point of 147° C. Further tests proved this to be tetrachlorethane, and it is postulated by the author that the high specific gravity of this substance explains why so little tetrachlorethane was contained in the stomach washings. No analysis of the other organs was carried out. In Elliott's case no details are given of the results of analysis of the stomach contents or of the viscera. Elliott states that "records of poisoning by this substance show that the fatal dose may be as low as 5 c.cm." He quotes no authority for this assertion.

It appears, therefore, that in cases of acute tetrachlorethane poisoning a fatal termination is brought about by narcotic action on the vital centres, and death supervenes so quickly that no effect on the liver, kidneys, and heart, of the kind seen in fatal cases of chronic poisoning by inhalation of the vapour, has time to appear. It is likely, however, that, should the patient survive the narcosis induced by a sublethal dose of the drug taken by the mouth, then he would show the symptoms of liver damage seen in cases of chronic poisoning by inhalation.

Chronic Poisoning

Many cases of chronic poisoning by inhalation of the vapour of tetrachlorethane have been reported, but the incidence of such cases in this country has become less frequent since the use of the substance in aeroplane factories was prohibited. However, in France and Germany tetrachlorethane is employed extensively in the manufacture of artificial pearls and as a constituent of an adhesive in the manufacture of shoes (Browning, 1937), and cases are still being reported (von Oettingen, 1937). Willcox had the opportunity of studying a number of cases of toxic jaundice due to tetrachlorethane poisoning, and he gives the following description of the symptoms, which correspond closely to those observed by various other workers.

> "For some days the patients complain of general malaise, drowsiness while at work, loss of appetite, nausea, retching in the morning, unpleasant taste in the throat, constipation usually, and headache. Abdominal discomfort is present in some cases. After indefinite symptoms of this kind lasting several days or even weeks definite jaundice develops, and this is associated with pale stools and bilious urine. Vomiting is now likely to become more marked. The patient may become mentally confused, stuporose, and delirious. In acute cases haematemesis or convulsions may occur. Coma supervenes and death results. In the toxic stage of the disease purpuric rash and haemorrhages may occur. Suppression of urine also occurs towards the end. There seems to be a marked variation in the susceptibility of certain persons to the poison, and this corresponds to the varying susceptibility of patients to other liver poisons —e.g., chloroform."

It is generally agreed that young girls are particularly susceptible to the drug.

In some cases nervous symptoms first manifest themselves. These consist of tremors, headache, pain in the limbs, numbness, "pins and needles" of the extremities, loss of the knee-jerks, and excessive sweating (Willcox, 1915). Some doubt as to whether these symptoms are due to tetrachlorethane alone or to that substance mixed with other toxic material is evinced by Browning.

Before obvious symptoms appear changes in the blood can be detected. From the study of 68 cases, Minot and Smith (1921) found that the blood changes in moderate poisoning consist of a mononucleosis with a marked increase of the endothelial leucocytes, and if the case progresses degenerative forms of these cells are seen. They also noted a progressive but slight anaemia and a slight increase in the number of platelets. They suggested that an increase of the large mononuclear cells to more than 12% should be regarded as the sign of a toxic action of tetrachlorethane, and that the appearance of a considerable number of young large mononuclear cells should be looked upon as indicating a severer condition than when the same number of mature large mononuclear cells was present. Parmenter (1920-1) used the changes in the blood as an indication of subclinical poisoning in workers in a silk mill, and in this way prevented the development of a single case of jaundice.

Post-mortem Findings

In fatal cases the liver is reduced in size and severely affected by fatty degeneration. If the disease runs a rapid course there are large areas of complete disintegration with fatty degeneration in the remaining liver tissue. There may be round-celled infiltration of the necrotic areas but no fibrosis or attempts at hypertrophy of the remaining tissue. When the disease is more chronic, replacement fibrosis and active hypertrophy may be seen (Spilsbury, 1917). Fatty degeneration also affects the myocardium and the kidneys (Rolleston, 1922). According to Spilsbury the jaundice is haemohepatogenous, obstructive in nature, and due to the inflammation of the small intrahepatic bile ducts by the direct action of the tetrachlorethane on the cells. A toxic fatty degeneration thus develops in the central zones and spreads through the lobules, leading to necrosis.

Animal Experiments

In animals the acute effects of tetrachlorethane inhalations resemble those of other chlorinated hydrocarbons, and death occurs from central respiratory paralysis. The chronic intoxication produces fatty degeneration of the liver. According to Browning, Müller did not find in his experimental animals the acute yellow atrophy of the liver characteristic of the human intoxication. He suggests that this may be due to the fact that, owing to their different alimentary metabolism, death occurs in animals before the "reactive inflammation" of acute yellow atrophy has time to develop. It has been found that tetrachlorethane applied to the shaved abdomen of a rabbit produces fatty degeneration of the liver by absorption through the skin.

Lehman (according to Hamilton, 1934) found that prolonged exposure to the substance caused emaciation, with evidence of damage to the liver and kidneys and of haemolysis, as shown by a low red cell count, stippled red cells, and haemoglobinuria. She also reports that Heffter and Joachimoglu observed similar changes, with in addition fatty degeneration of the kidneys and heart musculature. These changes were also produced experimentally in animals by Spilsbury and Willcox.

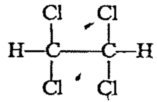
Case Report

At 6 20 p.m. on June 19, 1942, a labourer aged 33 was seen by a family friend to drink some fluid from a bottle which he had brought home with him. Thereafter he promptly went to sleep on a settee. The family thought he was sleeping naturally, until, at 10.30 p.m., attempts to arouse him proving unavailing, they realized that there was something amiss and sent for assistance. The patient was removed to hospital, where he was admitted at 11.50 p.m. On admission he was found to be deeply comatose, deeply cyanosed, and with shallow respirations. His breath had a sweetish smell suggestive of chloroform. In spite of attempts at resuscitation, which were started at once, his condition rapidly became worse and respirations ceased. Quantities of frothy fluid appeared at his mouth and nose, and he died at 12.30 a.m. on June 20—i.e., about 6 hours from the time he had ingested the toxic material.

Post-mortem Findings.—A necropsy was conducted on June 22, the following being the only noteworthy features. *Alimentary system :* There were no marks of corrosion round the mouth. The tongue, lips, gums, and oesophagus were normal. The stomach contained 1¼ oz. of watery fluid somewhat tinged with blood, which emitted a pungent sweetish odour. The mucous membrane along the lesser curvature showed intense congestion on the top of the rugae, the intervening areas being normal. The duodenum was also inflamed, the inflammation extending down to the upper part of the jejunum. The rest of the large and small bowels was normal. The liver showed no naked-eye evidence of fatty change or of necrosis; it was normal in size and the capsule was smooth. The pancreas was healthy. *Respiratory system :* The larynx and trachea were normal. Each pleural cavity contained some adhesions, and between these there was some serous fluid. The lungs were engorged and very oedematous, particularly at the bases, but were otherwise healthy. There were a few subpleural haemorrhages. The trachea and lungs smelt of the offending material. *Brain and meninges :* Congested. *Bladder :* This viscus contained 6 oz. of cloudy urine. *Histology :* The liver tissue was histologically normal and the lungs showed acute congestion and oedema, particularly at the bases.

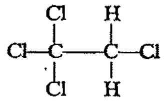
The bottle from which the deceased was seen to drink was recovered, and it still contained 9 c.cm. of yellow fluid, which had exactly the same smell as the stomach contents and lungs. It was obvious that it was the toxic agent responsible for his death. This fluid and the contents of the stomach and bowel, together with the liver, lungs, brain, and urine, were submitted to Dr. Mabel L. Hemming of the department of chemistry, Sheffield University, who very kindly undertook their analysis. She embodied her results in the following report:

"The original liquid was distilled and the boiling-point of the bulk corresponded to that of symmetrical tetrachlorethane: there was evidence of about 1 c.cm. (in a total volume of 9 c.cm.) of the lower-boiling isomer, unsymmetrical tetrachlorethane.



$$\mathrm{H{-}\underset{Cl}{\overset{Cl}{C}}{-}\underset{Cl}{\overset{Cl}{C}}{-}H}$$

Symmetrical tetrachlorethane ;
B.P. 147° C (normal pressure).



$$\mathrm{Cl{-}\underset{Cl}{\overset{Cl}{C}}{-}\underset{H}{\overset{H}{C}}{-}Cl}$$

Unsymmetrical tetrachlorethane ;
B P. 129–130° C. (normal pressure).

"A Carius estimation for chlorine on the distilled liquid indicated that it was probably 98% pure tetrachlorethane. Three estimations gave the following figures for the percentage chlorine in the liquid: 80.83, 81.27, 80.90, and the theoretical value for pure tetrachlorethane is 82.57%.

"Each of the samples supplied was treated in the following manner. The sample was minced up when necessary, and distilled in steam. When the liquid distilling over was no longer turbid distillation was discontinued and the steam distillate extracted with ether. The ether extract was dried over sodium sulphate and then the ether was distilled off through a Widmer column. The residue was analysed for chlorine by the Carius method, and hence the tetrachlorethane in the various parts could be calculated. The results are as follows: Stomach contents, 2.134 g.; liver, *nil*; lungs, 5 mg.; bowel contents, 1.47 mg.; brain, *nil;* urine, 4.32 mg. A blank Carius estimation was done and no measurable amount of chlorine found, suggesting that, although some of the above figures are very small, they are probably real."

Comments

Tetrachlorethane poisoning occurs as a chronic condition in which absorption takes place through the lungs or skin, and death is due to acute yellow atrophy of the liver. When seen in the acute form the poison is absorbed from the alimentary canal, and death results from central respiratory paralysis. The case reported above is similar to the two cases previously recorded by Elliott and Hepple. The results of the analysis support the view that excretion occurs partly by the lungs and partly in the urine. It will be noted that only relatively small amounts of the drug were recovered by analysis, but of course no estimation was made of the quantities in the blood, cerebrospinal fluid, muscles, etc. In addition, during the six hours which elapsed between ingestion and death an appreciable quantity of the material would have been excreted in the breath. I find it impossible, therefore, to estimate what the fatal dose was in this particular case, and unless the volume ingested is known I do not see how this would ever be possible with any degree of accuracy.

Summary

The clinical and pathological aspects of acute and chronic poisoning by tetrachlorethane are discussed.

Two previous cases of acute poisoning are reviewed and a further similar case reported.

My thanks are due to Dr. J. R. Grimoldby, resident surgical officer at the Royal Hospital, Sheffield, who supplied the clinical details reported, and to Dr. Mabel L. Hemming, of the chemistry department of Sheffield University, who undertook the analysis of the organs.

According to G. F. Dick and C. W. Eisele (*J. Amer. med. Ass.*, 1942, **118**, 21) the rate of healing of peptic ulcer under oral treatment with milk and cream, without the use of alkalis, compares favourably with other methods of treatment. They state that it is only the exceptional case in which recovery does not take place without alkali treatment.

EFFORT SYNDROME IN ICELAND

BY

D. E. RODGER, M.D., M.R.C.P.

Major, R.A.M.C.

During the fourteen months from April, 1941, to June, 1942, 83 cases of effort syndrome were observed among the British forces in Iceland. A review of these cases has been made in order to determine whether the conditions of service in Iceland, thought by some to be out of the ordinary, play any significant part in the development of the syndrome.

Observations

Of the 83 cases, 3 were from the Navy, 2 from the Air Force, 1 was a civilian employee (British), and 77 were from the Army. Of these men 63 (76%) were considered unfit for active service in the field and were returned to the United Kingdom as a result of a Medical Board examination (Category "D" or "E"—A.C.I. 1428/40). The remaining 20 (24%) were considered mild cases, and after suitable reassurance were returned to their units for full duties.

Age and Length of Service.—The average age in this series was 29¼ years (18–48), and the cases were distributed as follows: under 20, 1; 20–29, 44; 30–39, 32; 40–48, 6. The distribution corresponds roughly to the age-group representation in the Forces. Eleven had seen service before the present war; 67 had served during the present war only, for periods varying in length from three months to two and three-quarter years.

Seasonal Incidence.—Forty-three cases (52%) were seen during the inclusive period Nov., 1941, to April, 1942, and 34 (41%) during May to Oct., 1941.

Aetiology.—No cases were considered to have been directly caused by war service, but of the 63 cases evacuated five appeared to have been aggravated by war service. The first of these men suffered from hypermetropia, and claimed that "the light bothers my eyes" (see under "Discussion"). Reassurance did not improve his condition, and he eventually showed other features of the syndrome. Another, a reservist aged 38, felt he couldn't "keep up" with the younger men in his unit. A third, a company sergeant-major, went through the Norwegian campaign five weeks after an operation for bilateral inguinal hernia. The fourth case was that of a soldier who had always been employed in sedentary duties. He broke down shortly after coming to Iceland when he started intensive training. The symptoms in the fifth case appeared after hospitalization for "acute rheumatism" in Sept., 1940.

Attributability.—All of the 58 cases considered unconnected with war service that were evacuated showed either a poor family history or a past personal history of "constitutional inferiority," or both. It was not difficult to reveal the familiar historical pattern of an over-protective parent firmly implanting the conception of delicate health in the mind of the child or adolescent. The attributability in this series has been summarized in Table I.

TABLE I.—*Attributability of Effort Syndrome*

Attributability	Number of Cases		
	Boarded	Returned to Duty	Total
Caused by war service	0	0	0
Aggravated by war service ..	5	2	7
Unconnected with war service ..	58	18	76
Total	63	20	83

Symptoms and Signs.—The symptoms exhibited were the familiar group fully described in Dr. Paul Wood's Goulstonian Lectures for 1941. The relation between the onset of symptoms and service in Iceland is shown in Table II. Investigation of the patient included a history, physical examination, and radiological examination of the thorax. It was exceptional to admit these cases to hospital. In common with other observers, an increase in the pulse and blood pressure was noted. The average blood pressure of 70 cases was 141.6/84.2. The highest systolic pressure was 174 (diastolic 74). The highest diastolic pressure was 112 (systolic 164). As expected, the diastolic pressure fell to 90 after two days in hospital. The mean pulse pressure was 57.4 mm. Hg. The exercise-tolerance test was not found to be of diagnostic value.

TABLE II.—*Date of Appearance of Effort Syndrome*

Date	Number of Cases		
	Boarded	Returned to Duty	Total
Before service in Iceland	59	15	74
Subsequent to service in Iceland ..	4	5	9

Differential Diagnosis: Hypertension.—A systolic pressure above 170 mm. Hg or a diastolic pressure persistently above 100 mm. Hg is required for a diagnosis of hypertension. These are admittedly arbitrary figures. But in the absence of other findings a systolic pressure of 170 mm. or less and a diastolic pressure under 100 mm. were considered within the limits of normal.

Discussion

The unusual features of service in Iceland that might be thought productive of the syndrome can be summarized as follows:

1. *Topography.*—Iceland is a mountainous country devoid of trees, and with sparse vegetation. The earth's surface is very uneven, being covered with much broken lava rock, varying in size. This makes walking a more attention-claiming pastime than it is elsewhere.

2. *Climate.*—Because of the country's latitude there is a long period of daylight during the summer months and a short period of daylight during the winter months. It is held by many that the light is "stronger" than elsewhere, but this is considered to be fallacious. Both the ophthalmologist and myself have often been confronted with the complaint, "It's the strong light, sir" (cf. case mentioned above). On the other hand, the shortness of natural light in the winter means a long dark day, which might result in introspection, boredom, and depression. This appears to be adequately compensated in the normal individual by the absence of black-out regulations. The cold in Iceland is not intense, and it is generally held that the country has been misnamed. The snowfall is very moderate, and in most areas the snow rarely remains on the ground throughout the whole winter. On the other hand, training during the Icelandic winter of rain, mud, and darkness requires a robust physique and an equally robust mental outlook.

On the whole, these conditions have not been found to be causative factors in effort syndrome, but it is worth recording that the number of cases of effort syndrome referred increased considerably (*a*) during the period of intensive training, and (*b*) among the drafts of reinforcements from the United Kingdom shortly after their arrival in Iceland. The case incidence was slightly greater during the winter months (November to April), but this was also the period of intensive training and when drafts of reinforcements were arriving.

The great majority of these cases were already psychologically predisposed to develop the syndrome. This they did when they were confronted with the physical and psychical difficulties of "active service in the field." The small number of cases occurring among Naval and Air Force personnel was not accounted for by the numerical proportion of these Services in Iceland: perhaps the explanation lies in a greater selectivity of candidates for them.

The subsequent history of the more severe cases is not known, as they were evacuated.

Summary and Conclusions

Eighty-three cases of effort syndrome have been observed among British troops serving in Iceland; 63 of these were considered temporarily or permanently unfit for military service.

The conditions of military service in Iceland are not considered causative factors in the development of effort syndrome. They are regarded as aggravating factors to a minor extent only.

The number of cases brought to light increased during the intensive training and following the arrival of drafts of reinforcements from the United Kingdom.

Simple explanation and return to duty at the unit have been successful in some of the milder cases of the syndrome.

I wish to thank Col. S. D. Reid, A.M.S., for permission to publish this paper.

Medical Memoranda

Severe Gunshot Wound of the Abdomen

The following report of a case of severe gunshot wound of the abdomen, occurring on board one of His Majesty's transports in mid-ocean, is of interest.

CASE HISTORY

A gunner aged 26 was accidentally wounded by a rifle bullet in the abdomen at 11.50 a.m. on April 17, 1942. The bullet, before wounding him, had passed through the hand of another soldier. The gunner was seen five minutes after the injury lying on the ship's lowest deck, holding his abdomen. He was very pale and in great pain. Morph. tartrate 1/2 gr. was given immediately. On disengaging his hands and unbuttoning his battle-dress it was found that most of the small intestine, the caecum and appendix, and a large portion of the omentum had prolapsed and were lying over the pubic region and between the thighs. The lower portion of a vest partly covered the viscera, the remainder lying free in his trousers. Six or seven shell dressings were needed to gather up the loose bowel and to hold it in place outside the abdomen. The bandage ends were gently passed around the trunk and fixed with pins. He was then placed carefully on a stretcher, with two life-jackets under the flexed knees and four life-jackets behind the shoulders and head. In this position he was carried up through four decks to the ship's hospital. Twenty-five minutes later he was given 600 c.cm. of fresh blood, and at 12.50 p.m. was placed on the operating table, not having been previously moved off the stretcher.

Operation.—Under a general anaesthetic (open ether) the whole of the prolapsed bowel was covered with sterile gauze pads partially wrung out in 1/20,000 aqueous solution of euflavine. More gauze swabs, similarly treated, were partially introduced over the wound edges into the abdomen by raising the prolapsed bowel at the wound perimeter, as a preliminary to the replacement of the bowel after inspection. The only visceral damage discovered was an abrasion of the ileum, 3½ in. long and 1/4 in. wide, involving the outer coats of the bowel: this was longitudinally inverted with Lembert sutures of fine catgut. All the prolapsed bowel was then replaced within the abdomen and covered with omentum, which had escaped injury. The whole abdominal wound was now in view. It was large and gaping and of the size of a hand, equidistant between the umbilicus and pubis, and was obviously caused by a splayed bullet running from side to side, gouging away in its path all the structures of the abdominal wall. The wound edges were then excised, and by flexing the spine the retracted peritoneal edges were approximated and completely sutured. The right rectus muscle was deficient for about 3½ in.; this was repaired by sliding across the damaged but not deficient left rectus and anchoring it with interrupted sutures, over which the anterior sheath was closed, haemorrhage from the inferior epigastric having been controlled. The internal and external oblique aponeuroses were closed by interrupted sutures. The skin wound was closed without difficulty by interrupted sutures, over which two rolls of flavine-soaked gauze were placed and held in position by six deep tension sutures. The skin wound resembled a large "Y" with a very short vertical limb, the two oblique limbs each being drained by a rubber tube inserted down to the superficial muscle plane. The operation lasted two hours, at the end of which the patient's condition was good; his colour had returned and his pulse was steady at 78 per minute. He was then put into an adjacent single-cot cabin, where he was nursed for the remainder of the voyage.

Progress.—On his return to consciousness he was placed in Fowler's position and 500 c.cm. of saline was given subcutaneously. The following treatment was instituted: Inj. morph. hypoderm. 1/4 gr. four-hourly; pituitrin 10 units six-hourly; sulphapyridine, 3 g. statim, 2.5 g. three hours later, and 1.5 g. at three-hourly intervals till noon of the second day. (Sulphapyridine was continued four-hourly in decreasing daily doses until the end of the fourth day, by which time a total of 30 g. had been given.) His general condition six hours after the operation was good, and he was free from pain and able to take dextrose in water and weak lime-juice; temperature and pulse normal. Urine in adequate quantities was passed during this period. The blood count was normal. This happy state of affairs continued until midnight on the fifth day, when a feeling of distension was complained of. No bowel motion had as yet occurred since the operation, but enemata had been given daily and had prevented distension. By noon of the fourth day, however, signs of paralytic ileus became evident, and faecal vomiting occurred. Continuous rectal saline was then started and 2.5 units of pituitrin were given hourly together with morphine 1/4 gr. four-hourly. The patient's condition worsened considerably, but the temperature never rose above 99.4°. The morphine and pituitrin and continuous rectal saline were persisted with, and on the sixth day the patient's condition dramatically changed for the better with the passage of a large liquid stool. Within two hours he was comfortable and in excellent spirits, and demanded a cup of tea and a cigarette. As the ship's stock of pituitrin was now depleted, physostigmine was given in two-hourly doses of 1/200 gr., together with morphine eight-hourly. On the third day the wound was dressed and the drainage tubes removed, being replaced by lightly packed gauze swabs, which were renewed on the seventh day. Sloughing was considerable at the drainage exits, but otherwise the wound was satisfactory. On the eighth day, on arrival at a home port, the patient was transferred to a shore hospital; his condition was excellent and the bowels normal. Subsequent progress was rapid, though the drainage exits continued to discharge profusely. Although the wound itself healed well, it was considered advisable to explore the discharging sinus. This revealed a gauze superficial-drainage swab (which had replaced the original rubber drainage tube) that had been overlooked in the slough. The removal of the gauze was followed by rapid healing, and the patient was discharged to a convalescent hospital. Although the abdominal scars are extensive, there is no evidence of tendency towards ventral hernia. He has since returned to duty in a coastal battery in medical category C.

I wish to acknowledge with gratitude the services of Sister J. Douglas, T.A.N.S., of Edinburgh, to whose skill and devotion this patient's recovery is mainly due. I would also thank the medical superintendent of the E.M.S. hospital for his helpful notes on the patient's progress ashore.

W. P. GRIFFIN, M.B., B.Ch.,
Squadron Leader, R.A.F.

The Cotton-wool Sandwich

The swallowing of sharp-pointed foreign bodies presents a problem to the practitioner, often at a moment's notice, and provides a source of anxiety for him, his patients, and their relatives. I have recently been struck by the fact that so few doctors realize the value of the cotton-wool sandwich. The following case exemplifies the value of such.

Miss A. B., a dressmaker, was referred to the radiological department at the Whitehaven and West Cumberland Hospital on Sept. 9, 1936, because she had swallowed "a pin." My radiographer (Sister Hankinson, M.S.R.) screened her and took a film demonstrating the presence of 23 pins at all angles within the gastro-intestinal tract. She promptly gave the patient a series of small cotton-wool sandwiches, having impregnated the teased-out cotton-wool with a solution of barium sulphate in order, if possible, to follow the progress of the pins. Later in the day I saw the patient personally, and found one pin in the stomach, two pins in the duodenum, and a considerable number in the small bowel, mainly in the pelvis, intermingled with the barium-impregnated cotton-wool (Fig. 1). The pledgets of cotton-wool are seen mainly in the pelvic ileum. One pin was in the caecum, others in the descending and the iliac colon. The following day one pin was in the caecum and the rest were collected into four groups (Fig. 2)—one group in the splenic flexure of the descending colon, one in the iliac colon, and one at the proximal pelvic colon—all enveloped in the cotton-wool. A fourth small group is seen in the rectum, in which no wool is evident.

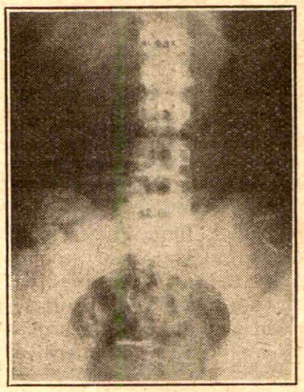

FIG. 1

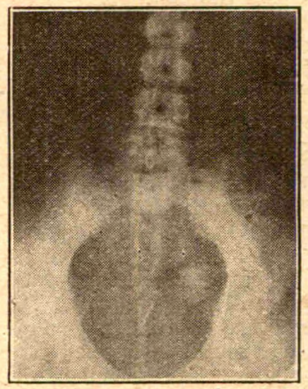

FIG. 2

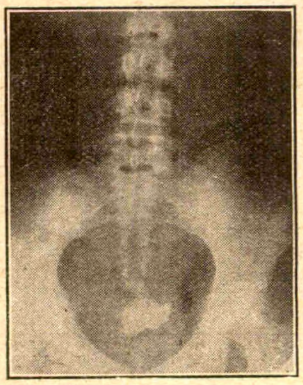

FIG. 3

The progress of the pins was checked up each day by radiological means. Each group was evacuated in turn at daily intervals: the film of Oct. 10 (Fig. 3) shows the last group enveloped in cotton-wool in the rectum. The following day all had been evacuated, without any pain or one drop of blood being shed.

Reviews

PREVENTIVE INOCULATION

Preventive Inoculation. By W Powell Phillips, M R C S, L.R.C.P, D.P H, and C. Woodroffe Anderson, M B., Ch B., D.P H With an introduction by J Greenwood Wilson, M D, F.R.C P, D.P.H. "The Practitioner Booklets" (Pp. 74 6s) London Published by the *Practitioner* in conjunction with Eyre and Spottiswoode. 1942.

If the practitioner is to take his proper place in preventive medicine he should be an enlightened apostle of the why, when, and how of prophylactic inoculation against the common infectious diseases of childhood, and, in wartime, such infections as typhoid and tetanus. In other words, he must be familiar with certain facts about the toll in life and health which these diseases exact, the means by which their ravages can be prevented or minimized by immunization, and the technical details for performing the necessary injections safely and effectively. It may be more convenient for the M.O.H. to arrange for the immunization of children to be done at the school or the welfare clinic, but he should, whenever possible, co-opt the family doctor for the work, so that the practitioner may gain the necessary experience and be a powerful ally (instead of a lukewarm onlooker) in carrying the propaganda into the home.

All the relevant information is admirably presented in this booklet from the "Practitioner Series," written by two public workers in close touch with the problems. Introductory chapters on the principles of infection and immunity are followed by practical advice on the preparation of apparatus and reagents, the technique of the injection, and the pitfalls to be avoided. Then come chapters on diphtheria, tetanus, scarlet fever, typhoid, pertussis, measles, and even influenza and the common cold, although the authors are rightly cautious about the prophylaxis of these last common plagues. It is pleasing to note their advocacy of immunization against pertussis; unfortunately the recent work of Bell on the efficacy of two doses of pertussis vaccine at a month's interval instead of 4 to 5 weekly injections came too late for inclusion in the text. Otherwise the book is remarkably up-to-date and can be heartily recommended.

A MEDICAL YEARBOOK

The 1942 Year Book of General Medicine Edited by George F. Dick, M D (Pp 848 19s) Chicago: The Year Book Publishers; London: H. K Lewis and Co.

The publishers of this useful yearbook have adopted the ingenious method of a questionary on the dust-cover, posing 20 questions of topical interest, to which the contents of the book provide the answers. We may assume that they regard these as the most important matters discussed, and will therefore concentrate on some of them. Rabbit thrombin is lauded as the best local haemostatic, effective even in haemophilia. Salyrgan-theophylline by the mouth is claimed as the best diuretic in congestive heart failure. When adrenaline fails to relieve asthma, intravenous aminophylline may do so, and will also restore the lost effectiveness of adrenaline. We are given a survey of the causes and prevention of unfavourable reactions to blood transfusion. A combination of steam and carbon dioxide is recommended as a powerful adjuvant to expectorant drugs, whereas oxygen has the opposite effect. In laryngeal diphtheria associated with measles sulphapyridine is advised, while for whooping-cough sulphathiazole is more suitable when bronchopneumonia supervenes. A safe and easy technique of paravertebral injections of alcohol is described for the relief of cardiac pain. A return of the sedimentation rate to normal is taken as the criterion by which to decide when a rheumatic child is to be allowed out of bed. The question of adequate liver therapy in pernicious anaemia is critically considered. The combination of ergotamine tartrate 0.25 mg., prostigmin methylsulphate 0.25 mg., and pituitrin 1.25 units is recommended as the most effective method of relieving post-operative distension and paralytic ileus, prostigmin being probably the best single drug. These few instances will give some idea of the variety of information to be obtained from a perusal of this interesting annual.

ALLERGY

Synopsis of Allergy. By Harry L. Alexander, A.B., M.D., Professor of Clinical Medicine, Washington University School of Medicine, St. Louis; Editor of the *Journal of Allergy.* (Pp. 246; illustrated. 15s.) London: Henry Kimpton 1942.

Dr. Harry Alexander follows his book *Bronchial Asthma*, 1928, with a *Synopsis of Allergy*, 1941. For the past twelve years he has held the post of editor of the *Journal of Allergy*, so no more appropriate person could survey the subject and describe allergy in terms of present-day thought. Only the non-bacterial types are dealt with. In a general discussion of allergy the diagnostic value of a careful history is emphasized. Protective measures against offending allergens, hyposensitization both against offending allergens and orally, and drug therapy are succinctly explained. The symptoms are then taken individually, and bronchial asthma, hay-fever, and the allergic dermatoses are discussed at some length, the other and lesser allergies very briefly. It is remarkable that the possibility of allergic headaches and migraine being due to inhalant allergy is not mentioned, the entire stress being placed on foods. An admirable appendix describes the preparation and standardization of extracts, lists household materials and foods and the allergens they may possibly contain, and gives recipes for elimination diets (not so practicable in this country under wartime restrictions, seeing that a wheat-free sponge cake requires four eggs!). The book can be recommended as an accurate, straightforward, and concise account of the subject for easy consumption.

ANAESTHESIA, WITH SPECIAL REFERENCE TO DENTISTRY

Essentials of General Anaesthesia By R R Macintosh, M.D, F.R C.S, D.A., and Freda B Bannister, M.D., D A. Third edition. (Pp. 341. 25s.) Oxford: Blackwell Scientific Publications.

The fact that the third edition of this book has already appeared although it was first published as recently as 1940 is sufficient indication of its merits. The general arrangement of chapters remains much the same, but the sections on reducing valves and general analgesia have been improved. It is, however, surprising that no reference is made to trichlorethylene, either as an analgesic or as an anaesthetic, although it is now widely used for both purposes. A chapter has been added on the principle and working of the Oxford ether vaporizer No. 1.

The chief criticism which can be made of the book concerns its title. The reader who, not unreasonably, expects directions for anaesthetizing patients for cranial, thyroid, thoracic, or abdominal operations will be disappointed, whereas dental anaesthesia is fully and excellently described. For this reason it cannot be recommended unreservedly for the use of medical students or general practitioners wishing to become familiar with anaesthetic technique generally. On the other hand, dental students and anaesthetists should profit much from its perusal The first edition had as a subheading "With Special Reference to Dentistry," but even this has now been omitted. If the book were called "Essentials of Dental Anaesthesia" its contents would be described more accurately.

The printing, paper, and illustrations are exceptionally good, and effective use has been made of colour diagrams—an unusual feature in a work of this character.

Notes on Books

The success of many pathological investigations depends largely on the proper collection of the specimen, which is often the duty of a nurse. Instructions to this end, together with brief accounts of the tests applied to all ordinary types of specimen and of their significance, are given in a pamphlet, entitled *Clinical Pathological Investigations*, by Dr. CYRIL POLSON (Leeds: Jowett and Sowry Ltd., 80, Albion Street; 1s., plus postage), which is based on lectures given to the nurses at St. James's Hospital, Leeds. Its study should form a useful part of a nurse's education, as well as acquaint her with methods of securing satisfactory specimens. The instructions follow generally accepted lines throughout except in a section on methods of sterilization; this needs simplification, and in some details correction to bring it into line with usual teaching.

BRITISH MEDICAL JOURNAL

LONDON

SATURDAY MARCH 20 1943

A UNITED FRONT

Statements by Government spokesmen in the recent Parliamentary debates on the Beveridge report made it clear that the present Government intends to take action on Sir William Beveridge's proposals for a comprehensive health service to be available to everyone in this country. They made it clear that the responsibility for administering such a service is to devolve on local bodies. They also made it clear that there was to be no proscription of private practice, and no violation of the voluntary hospitals. Since the closure of the debate the Minister of Health has called a meeting of representatives of the principal medical organizations, including the British Medical Association, to hear his views on the procedure to be adopted in the consultations that are to take place in the coming months between the Ministry and the medical profession. The Ministry has also held meetings with representatives of the voluntary hospitals and of local authorities.

The Minister of Health has asked the medical profession to form a representative committee to consider with him and his officers the difficult problems that will have to be solved if a comprehensive National Medical Service is to be put into shape. Discussions on the matter have already taken place between the British Medical Association, the three Royal Colleges, and the Society of Medical Officers of Health, and in the general statement on the present position issued by the Secretary of the B.M.A., Dr. G. C. Anderson, and printed elsewhere in this issue, the proposed personnel of such a committee is set forth. At its meeting on March 31 the Representative Body of the B.M.A. is to be asked to endorse the view that the proposed Committee can be taken to represent the medical profession in the discussions that lie ahead. One thing should be made clear at once, and that is that such a committee will not have plenipotentiary powers. It is not a negotiating body, and the medical profession is not being asked to give it a "doctor's mandate" to come to binding agreements or to seal any bargain with the Government behind the backs of the profession at large. Whatever plan the Government may unfold, it is quite clear from the letter from Sir John Maude, secretary to the Minister, included in Dr. Anderson's statement on another page, that the representatives of the medical profession will be in continuous conference with the Ministry. The Minister asks for the "frank expression of the opinions of those best qualified to judge both on issues of a technical and professional kind and, what is no less important, on the probable attitude of the profession towards any proposals that may be put forward." It would seem probable that from the Representative Committee small subcommittees will be formed to deal with the special issues under discussion at any one time.

The most important statement in Sir John Maude's letter refers to the intentions of the Ministry not to submit any proposals to Parliament on behalf of the Government until the profession has had laid before it a general indication of what these proposals are to be. Sir John goes on to say that in this way representatives of the profession will have ample opportunity for discussion and reference back to constituent bodies, and that the Government, in framing any time-table, will not forget that many of the profession are serving over-seas. The Association itself plans to inform each Service member individually of the Government proposals when they are made and to take steps to have the views of Service doctors assessed and presented to the Representative Body. This is a specific undertaking and not a vague expression of good intentions. It is realized that to circularize Service doctors in this way and to collect and collate their views will take time. It is also realized that the circumstances of war will make communication with some doctors impossible. But the attempt will be made, and made with the determination to obtain the maximum result possible in extremely difficult circumstances.

The history of medical organization is for the most part a history of dissension, of petty squabbles, of narrow sectional views. Surgeons bickered with barbers. Physicians despised both, and for five hundred years warred against the apothecaries. When the apothecaries became respectable they tried to crab the chemists and druggists. In the fifteenth century a Conjoint College of Physicians and Surgeons lasted only for two or three years. Now in the twentieth century the visible bond between the two is a conjoint examination and a standing joint committee with their new sister College. We have on the whole tended to perpetuate the errors of the past rather than to emulate the few attempts at unity that were made. But the profession is learning that its common interests are greater than its common differences. The setting up of the Medical Planning Commission by its various constituent bodies was a conspicuous demonstration of this; yet this act of unity was fiercely criticized in these columns at the time. To-day the Colleges have again thrown their weighty influence into the common scales. This week we announce the composition of a body appointed by collaboration between them, the B.M.A., the Society of Medical Officers of Health, and the Medical Women's Federation. In the past the Colleges have often tended to act in isolation, and their decision once more—at a most critical moment in medical history—to stand on common ground with the other organizations will be warmly welcomed by their numerous licentiates and members, as well as by their Fellows.

The Government has declared its intention not to spring surprises in unilateral action. No doubt there will be plenty of disagreement, but this can be voiced. And in the last count the profession itself will be able to express its views and press them home before legislation is passed. To use an old slogan, it must preserve a "united front" in the difficult months that lie ahead. The Representative Committee must have the good wishes of the profession behind it, and will, we are sure, command the support of every doctor of good will.

THE REHABILITATION OF THE FLAVINES

The antiseptic treatment of wounds during the war of 1914-18 was generally considered a failure, and antisepsis has since then been commonly regarded as an outmoded method. That is not to say that it was ever totally abandoned, but persistence in its use has been due to habit and custom rather than to any conviction of its efficacy. Little has been expected of it, and in general little has been achieved by it. That this attitude has been abandoned and the antiseptic method restored in surgical estimation to a position far more secure than it ever held in the past is due in the first place to the discovery that sulphanilamide acts locally as well as systemically. To anyone who studied the work of Fildes and Woods on the action of sulphanilamide on the haemolytic streptococcus it became abundantly plain that this compound is an antiseptic in every sense of the word: the nature of its action on bacteria is in fact the same as that of mercury perchloride. The difference between them is that sulphanilamide has a very low toxicity and can be maintained in adequate concentration and in free form throughout the body fluids, whereas mercury salts are highly poisonous to the body itself and cannot exist free because they combine with proteins. As soon as it was established that solid sulphanilamide is an efficient local preventive of infection, antisepsis regained repute, and minds were reopened to the possibilities of other agents for the same purpose. These others were both old and new, and among the new the astonishing properties of penicillin have attracted most attention, although the scarcity of supplies has so far prevented extensive clinical trial. Penicillin is suitable also for systemic use; another "biological" antiseptic, gramicidin, is recommended only for local application, as is propamidine, to which we have referred recently.[1]

Of the older antiseptics only the flavines have shared in this restoration to favour, a fact which has been no surprise to their few faithful advocates during the sceptical interwar period. The champion of these antiseptics since their earliest days, C. H. Browning, contributes at page 341 a restatement of their properties with an assessment of their position in the light of recent observations. It is noteworthy that the main facts, including the vital experimental evidence that acridine compounds will sterilize dangerously contaminated wounds, have been known for over twenty years. This work was done in part by Browning himself, by several workers in Germany, and by one in Japan, and taken together it forms an impressive bulk of evidence which has been inexplicably disregarded. Although these experiments have taken several forms, and employed various acridine compounds and different bacteria, they have regularly shown that these compounds will avert an otherwise fatal infection if applied to tissues into which virulent bacteria have recently been introduced. This could be said of no other antiseptic until the advent of the sulphonamides; indeed, control animals in some of these experiments were treated with such substances as phenol and mercury perchloride without effect. It has also been well known since their introduction that the flavines are comparatively non-toxic; they can be not only applied to exposed tissues without causing evident damage but injected interstitially, this being the proper treatment of a dangerous punctured wound. Short of causing actual necrosis an antiseptic may admittedly do harm by damaging individual types of cell, and the toxicity of the flavines for leucocytes is the subject not only of a now historic controversy but of conflicting observations even within the past few years. So completely discordant are some of the results reported that, as Browning says, they serve only to condemn some of the methods by which they were obtained. The weight of evidence on this point is that leucocytes will at least survive exposure to flavine concentrations which are bactericidal, even though their phagocytic capacity may be impaired.

It may well be asked why, if the flavines have these outstanding merits, their clinical performance has not been correspondingly successful throughout their twenty-six years' history. There are two answers to this question: wrong choice of compound and misapplication. The existence of three different acridines—apart from proprietary compounds such as rivanol and vuzine—popularly regarded as interchangeable, but in fact having quite different properties, has been an obstacle to successful use, particularly since acriflavine, the most popular, is now known to be the least satisfactory. A. Albert, who has synthesized a number of new acridine compounds, two of which are highly promising, drew attention five years ago to the superiority of proflavine, and this was strikingly illustrated by Russell and Falconer in their tests on the exposed rabbit's brain. The application and injection of solutions of acriflavine and various antiseptics of other kinds caused a severe haemorrhagic necrosis, but a neutral isotonic solution of proflavine caused no more apparent damage than normal saline. Proflavine is therefore the compound of choice, and there is recent experimental evidence in the work both of Hawking and of McIntosh and Selbie that it is an efficient wound prophylactic; indeed, in the prevention of gas gangrene it appears to be superior to the sulphonamides. There is no corresponding evidence from the clinical field, because no organized attempt has been made to obtain it, whether in dealing with war wounds or otherwise. The new clinical evidence refers not to prevention but to the treatment of established infection, a totally different problem and one presenting greater difficulties. It is here that the method of application becomes most important, because it is clearly necessary that the antiseptic should not only penetrate every part of the wound but persist there in adequate concentration for a considerable period of time. Of the two chief methods used in the past neither was calculated to achieve this. The drawback of a wet dressing is that all the antiseptic dyes, including the acridines, have an affinity for fabrics, and tend rather to combine with than to diffuse away from them. The *B.P.C.* acriflavine emulsion—perhaps the commonest form in which any acridine compound has been used for twenty years past—is so constituted that almost none of the acriflavine can escape from it, and it is therefore of no more value than simple liquid paraffin. The solution to this problem, which proves to be simplicity itself, was found in Libya by Mitchell and Buttle, who introduced proflavine into wounds by the same method, though not in the same quantity, as sulphanilamide—namely, as a powder. The solubility of proflavine sulphate is about 1 in 300, and by analogy with what is known of the relation between solubility and persistence in wounds among the sulphonamides, it may be deduced that under given conditions a moderate amount of proflavine will take at least two days to undergo complete solution, and will therefore act in full concentration throughout that time. The results obtained by this treatment, even in cases of intractable suppuration, were often dramatic. These are good reasons for saying that the flavines have come into their own again; proflavine has indeed come into rather more than has ever been claimed in the past. It should certainly be given further trials in comparison with other agents for both prevention and treatment of wound infections.

---

INDUSTRIAL HEALTH AND HYGIENE

Two important announcements with regard to the promotion of industrial health were made by Mr. Ernest Bevin, Minister of Labour and National Service, at a conference in London on March 11. The first was the setting up of an Industrial Health Advisory Committee attached to his Department. He explained that the Industrial Health Research Board, which had existed since the last war, would continue; but that was a body engaged on long-term inquiries, whereas the new Committee would concern itself, through its panels, with immediate improvement of industrial environment and diminution of health hazard, and would include engineers, chemists, physicists, and representatives of employers and trade unions, as well as medical men. The other announcement concerned a three-day conference on industrial health, to open in London on April 9.

Mr. Bevin said that industrial health had been rather relegated in the past to a separate compartment. The ordinary general practitioner had not had very much knowledge of the actual conditions of industry and had tended to regard industrial health as a matter for the specialist. But during the war there had been great improvement. The services of a large number of part-time works doctors had been enlisted, and liaison had been obtained between works doctors and outside medical services. The great trouble was the shortage of medical men. But he added that industrial health was not entirely a medical problem. Such a question as the design of factories and offices came in, and it was important for employers to have advice on planning and lay-out. The employer naturally sought to get the utmost out of his machines, but he had also to study the human factor, and it had been found, rather paradoxically, that a slight slowing down of the rate of production actually increased production. When machines were working at their full capacity the nerve strain was very great, and there was so much "standing off" and introduction of new workers on account of the exhaustion of those whom they replaced that better results were obtained by a certain slowing down.

Another important factor was the development of safer materials and methods and more effective safeguards. Mr. Bevin gave as illustration the discovery of a harmless substitute for yellow phosphorus in the manufacture of matches, the introduction of leadless pottery glazes, and the substitution of solvents less toxic than benzene and carbon bisulphide in rubber cements. It would be the duty of the new Committee to keep step with every new discovery in order that the best possible use of it might be made. He believed also that methods of lighting and ventilation were still in their infancy, and that great scientific developments in these respects which were now used for war purposes would in time become available for industry generally. The Committee would also concern itself with nutrition. The Ministry was extremely anxious to maintain the present feeding arrangements after the end of the war, because it had been clearly shown that they were one of the great checks against industrial ill-health.

In passing he paid a tribute to the factory inspectorate, medical and other; they had never received enough publicity. The combination of medical with other inspectors had led to good results. The Committee would develop the machinery of inquiry (as distinct from research) into industrial health questions by increasing facilities for *x*-ray examinations, examinations of blood samples, medical supervision of particular cases of illness, and so on. Soon after he came to office he issued an order relating to medical services in factories. Many employers who opposed him very much at the time now told him that this had proved to be one of the greatest economies ever introduced into the industrial system. He believed that the development of medical services in factories would go on after the war by its own volition, and that among the qualifications for good managership would be reckoned an interest in and knowledge of industrial health and hygiene. What was needed was a greater exercise of the experimental mind in this respect. A good deal of progress was made during the last war, but with the great unemployment period there was a setback. He paid a tribute to the pioneer work of Sir Thomas Legge, the first medical inspector of factories. It was such work as his to which it was now desired to give further impetus.

In reply to a question as to how the recommendations of the Committee would be implemented, Mr. Bevin said that where regulations were necessary these would be operated through the Factory Department of the Ministry, where social change was necessary they would be operated through the Welfare Department; and where scientific development was called for, through the various scientific bodies.

OCCUPATION AND THE MOUTH

An article by Schour and Sarnat[1] on oral manifestations of occupational origin is of topical interest now that so many practitioners have entered the factories to promote health in industry. The oral cavity is especially prone to occupational disease. Foreign substances which are inhaled or ingested during talking, laughing, and eating tend to collect and stagnate in the mouth, especially along the gum margins of the teeth. The rich blood supply, too, although it promotes resistance to infection, brings to the oral cavity substances which may have been absorbed elsewhere. Thus the soft tissues and the bone may be affected by local or systemic irritation, but the exposed enamel and dentine, being both avascular and acellular, are affected only by local factors. The teeth may be injured mechanically, often in a way characteristic for the occupation—for example, by threads, tacks, nails, or similar articles held in the mouth. Dusts such as cement and sand produce generalized abrasion, and acid fumes decalcify the dentine and enamel. Damage to the soft tissues by acid fumes, or gases such as ammonia, chlorine, and bromine, may favour secondary infection and Vincent's ulceration. Chronic and recurrent irritation, as in food-tasters, glass-blowers, and cobblers, may give rise to leukoplakia and carcinoma. A high incidence of tooth decay has been reported among workers in sugar dust, which is deposited on the labial aspect of the gum margins, where it stagnates, with consequent fermentation and formation of acid. The "sugar caries" which results is highly characteristic. The crowns of the teeth may be stained various colours by metallic dusts, but the staining is superficial and is removed by proper cleaning. On the other hand the gingival lines of lead, bismuth, and mercury are due to the deposition of the sulphides of the heavy metals in the dermis. Phosphorus, mercury, and radium affect the alveolar bone. In the early stages the disease may not extend beyond the apices of the teeth, but in the later stages the osteomyelitis may include the greater portion of the jaws and be followed by sequestration. Gingival bleeding, ulceration, and necrosis of the maxilla may also result from exposure to benzene, as a result of the toxic action on the blood-forming organs.

Almost all the oral manifestations of occupational origin are predisposed to and aggravated by neglect of oral hygiene. In fact, the presence of the aetiological agent alone is not enough to cause oral disease; the general and the oral health of the patient are equally important. In other words, oral hygiene is an essential part of industrial hygiene. Nevertheless, nutrition surveys and the observations of medical officers entering industry since the war have shown that the essential basis for oral hygiene in the factory is lacking in this country. The state of the teeth of the worker is lamentable—widespread caries and gingivitis, and up to 50% edentulous before the age of 30. It is almost certainly due in large part to the malnutrition that was so prevalent before the present war.[2] The situation can be remedied only by a better standard of nutrition, better education of the public, and better provision for the prevention and treatment of dental disease during the years of growth. Until it is remedied, the task of the dentist trying to practise conservative dentistry in the factory and to improve oral hygiene in the workers is not an enviable one.

BRAIN VOLUME DURING ANAESTHESIA

Swelling of the brain during an intracranial operation is serious and may be such as to make the operation difficult, if not impossible. White and his co-workers,[3] in some studies on cats from which the brains were removed and examined when various conditions of anaesthesia had been reproduced, have shown which factors lead to brain swelling and how they may be avoided. The anaesthetics used were pentobarbital sodium (nembutal), nitrous oxide, and ether. Anoxia, from obstruction of the respiratory tract, from failure of the respiratory centre, or from an inadequate volume of oxygen in the inspired mixture, always led to swelling of the brain by exudation of fluid from the capillaries. Nembutal and ether did not of themselves cause swelling of the brain, but did so in the presence of anoxia. Anoxia from obstruction of the respiratory tract can be avoided by endotracheal intubation, which is, therefore, important in general anaesthesia for neurosurgery, and is recommended by the authors as a routine for this work. Nitrous oxide should not be used alone for craniotomies because reduction of the inspired oxygen percentage below 10%, or any oxygen saturation of the arterial blood below 80%, led to brain swelling. The slight apparent swelling of the brain under ether from its vasodilator effect on the cerebral vessels was not considered significant, and when it occurs in man is not disturbing to the surgeon. The authors found that engorgement of the cerebral vascular bed was not related to anoxia *per se*, but to an increase in the tension of CO_2 in the arterial blood. Hypercapnia can occur in general anaesthesia, and should be avoided by using endotracheal anaesthesia and by ensuring that CO_2 cannot accumulate because of a faulty anaesthetic machine. Whereas, experimentally, anoxia and hypercapnia have been studied separately, in poor general anaesthesia they generally occur together, and when there is severe respiratory obstruction which prevents adequate intake of oxygen and output of CO_2 there may be such extreme swelling and congestion of the brain that it entirely fills the cranium and herniates through the operative defect.

The importance of adequate oxygenation of patients with head injuries is discussed by these authors and also by Schnedorff and others,[4] who have shown that in experimental concussion in dogs and in cerebral injuries in human beings the oxygen saturation of arterial blood may fall well below the critical level at which exudation of fluid from the capillaries occurs. Most of the patients who die come into this group, but those with oxygen saturation above the critical level recover. A warning of especial importance in wartime is that removal by aeroplane of patients with cranial injuries is dangerous. There are changes in the volume of the cranial contents at about 11,000 feet; atmospheric oxygen is reduced to about 15 vols. %, at which level in the normal individual arterial oxygen tension falls to about 85%.

SURGERY OF COMMUNICATING HYDROCEPHALUS

When progressive hydrocephalus is not due to obstruction to the flow of cerebrospinal fluid, it is logical to limit the secretion of fluid by destroying the choroid plexuses. Scarff[1] has reported upon the results of a series of endoscopic cauterizations of the choroid plexuses, using an improved ventriculoscope, which he first described in 1935. Putnam[2] had previously recorded a method of introducing a lighted instrument through a burr hole into the large ventricles of hydrocephalic children. Good illumination of the choroid plexuses was obtained, and it was found possible to cauterize them under direct observation without an extensive operation. Unfortunately, leakage of fluid caused a fall in pressure, followed in some cases by collapse of the patient. Dandy,[3] who first attempted destruction of the choroid plexuses by open operation in 1918, attributed his fatalities to this collapse, and described the falling in of the thin cerebral hemispheres. Scarff maintains the pressure by means of a reservoir of fluid connected to the ventriculoscope, which can be raised to equal the intraventricular pressure. At first he used Ringer's solution, but he has found a solution of sodium, potassium, calcium, and magnesium chlorides—"artificial cerebrospinal fluid"—to be more easily tolerated. His operative technique is similar to Putnam's and his results are interesting and encouraging. He has performed 48 operations on 20 patients, cauterization of the plexus on each side counting as two operations. Three children died as a result of the operation, and it seems that in each case death was due to sudden fall in intraventricular pressure after the patient had returned to bed. He later prevented a similar catastrophe by promptly restoring the pressure with an intraventricular needle connected to a reservoir of artificial spinal fluid. Although his total operative mortality is 6%, Scarff has had no deaths in the last 4 years. Seven (35%) of the surviving children were not greatly improved, but the other 10 (50%) have maintained a reduced intracranial pressure for periods ranging from 6 months to 6 years. Of these, 4 are mentally quite normal and 3 are only moderately retarded. Moderate hydrocephalus in childhood often becomes stationary, and is not necessarily accompanied by backwardness, but in all Scarff's patients there was progressive and even great enlargement of the head before the operation, while his clinical photographs show very convincingly the results he has achieved. Non-obstructive hydrocephalus is, of course, only one of the many causes of cranial enlargement in early life, and Scarff rightly stresses the importance of careful investigation, including a ventriculogram and a dye test—recovery of dye introduced into the ventricles by lumbar puncture. This must be followed by careful selection of cases, radical cauterization, and a most meticulous post-operative observation, for the good results depend upon timely intervention and sometimes upon a further operation.

Sir Charles McMoran Wilson, President of the Royal College of Physicians of London, who was created a baron in the New Year Honours, has taken the title of Baron Moran of Manton in the County of Wiltshire.

DECREASE IN ADMISSIONS TO MENTAL OBSERVATION WARDS DURING WAR

BY

FREDERICK HOPKINS, M.D.

Consulting Psychiatrist, Smithdown Road Hospital, Liverpool

Much has been thought and written about the effect of war conditions on the neuroses, and it is generally agreed that there has been little or no increase even among populations who have been subjected to the heaviest enemy action. Less attention has been given to the influence of war conditions on the incidence of the more grave mental disturbances of psychotic nature. The facts regarding this subject are not easily ascertained, but it has seemed to me that it might be worth while to consider some statistical details relating to a particular area, and that these, taken together with similar details from other areas, might have a general implication.

It is impossible to state the actual incidence of mental disturbance in any given community, but it can be said that the great majority of persons whose mental condition or behaviour demands restraint and/or supervision must be admitted to suitable institutional care. In this area, except with those individuals—a small proportion—whose means allow of private care, or in cases in which voluntary admission to county mental hospitals is arranged direct, such persons must in the first place go into a mental observation ward. The variation in the number of admissions and of types of disorder should therefore have some significance in relation to the population as a whole.

Yearly Figures for Liverpool

The mental observation wards, male and female, for the whole of the administrative and "user" area of the City of Liverpool, supplying a population of upwards of a million, are confined to a section of one large municipal general hospital. It was therefore decided to note the yearly total of admissions to these wards for each of the first three years of the war and for the three years preceding it, calculating each year from Sept. 1 to Aug. 31. It would have been interesting to make a diagnostic classification, but to do this accurately is quite out of the question in view of its inherent difficulty and of the often short period of stay in hospital. There are, however, several conditions in which a definite diagnosis is available, and three fairly common reasons for admission for observation are those of attempted suicide, epilepsy, and G.P.I.

Cases in Female Wards

	1936–7	1937–8	1938–9	1939–40	1940–1	1941–2
Admissions	603	631	570	465	395	357
Attempted suicide	64	66	66	39	27	34
Epilepsy	35	40	33	37	21	26
G.P.I.	11	11	13	4	3	7
Discharges	631	623	581	464	402	383
To mental hospitals	183	160	142	108	105	112

Cases in Male Wards

	1936–7	1937–8	1938–9	1939–40	1940–1	1941–2
Admissions	530	547	484	493	374	338
Attempted suicide	65	68	82	61	38	31
Epilepsy	44	35	28	18	15	21
G.P.I.	21	26	22	17	12	14
Discharges	529	551	485	519	404	340
To mental hospitals	110	107	122	138	135	131

The yearly total of admissions for mental observation, both male and female, is given, and the yearly number of those who were transferred to mental hospitals. The difference between the latter figures and the total discharges for each year is accounted for by the number of patients who were discharged to their friends or relatives and to other wards or hospitals (no longer requiring mental supervision), or who died. It will be seen that a steady fall in the number of admissions began from the year preceding the outbreak of war, and that there was a very pronounced drop from 1936-7 to 1941-2. The numbers of cases transferred to mental hospitals show some variation, but this has no immediate significance as regards the incidence of mental disorder, patients being transferred only when vacancies at mental hospitals are available.

Commentary

Is the great reduction in the admissions indicative of a decrease in the incidence of mental disorder? The figures may have been influenced by several factors, such as a lowering of the population of the area, admission of psychopathic individuals into the Services, an increase in the number entering county mental hospitals directly as voluntary or temporary patients, the evacuation of the more unstable types of individual to "safe" areas, and possibly increased admissions into hospitals from safe areas. Though these factors may have played a part, it is to be observed that the number of transfers to mental hospitals on certificate from this hospital has shown no notable change and that there is a fairly constant hard core of the more intractable, more severe, or chronic cases which require longer institutional care. It would appear, then, that the reduction in admissions applies mostly to the less severe, less urgent, and more transient cases; and it would seem reasonable to assume either that such cases remain at home or that they occur less frequently. The former explanation is unlikely, because it seems that in families in wartime there is less willingness or ability to give the care and supervision necessary for mentally handicapped members. Indeed, a relative increase of old people and of mentally defective individuals is noticeable among the admissions, patients coming into hospital who show disabilities of long standing but who previously had been cared for in their own homes. Diagnostic classification of all the admissions might have thrown some light on this question, but as it has been impossible to do this with any reliability the investigations have been confined to the three conditions shown in the tables. The figures for epilepsy and G.P.I. show a downward trend during the war years, but the significance of this can only be a matter for speculation. The marked decrease in suicidal attempts, however, is striking, and may have some relation to the general decrease in admissions.

Conclusion

It seems to me that the above figures point to a decrease during the war in the incidence of mental disturbance, and that this decrease is the result of wartime conditions. Of these conditions the chief factors appear to be the increased opportunities of employment, the strengthening of the community spirit, and a lessening of that consciousness of mental isolation which is so favourable to the development of psychological abnormality.

Acknowledgment is made to Dr. J. P. Steel, medical superintendent of Smithdown Road Hospital, for permission to publish these figures.

THE EMPIRE RHEUMATISM COUNCIL

The sixth annual report of the Empire Rheumatism Council announces that an agreement on joint policy has been reached with the British Orthopaedic Association, one of the items being that orthopaedic hospitals or orthopaedic departments of general hospitals shall include on their medical staffs a physician with a special knowledge of rheumatic diseases, and rheumatism centres shall include an orthopaedic surgeon. To put the policy into effect a standing advisory committee has been constituted, with Lord Horder as its chairman and Mr. G. R. Girdlestone as vice-chairman. The report mentions increased pressure on the very few treatment centres in industrial areas. It is true that some of the spa institutions are not fully utilized, but, valuable as is the part which they can take in rheumatism treatment, obviously they cannot meet the needs of the many thousands of sufferers who require facilities near their homes. Clinics in London—the Red Cross Clinic, the clinic of the Order of St. John, and the clinic at the West London Hospital—are working to capacity or beyond it, and other treatment centres in England and Scotland report that their services are fully utilized. The statistics of the clinics show that about 60% of the patients obtain cure or substantial relief if they receive the right treatment at an early stage, and this without serious disturbance of their industrial and domestic life. The fact remains, however, that the number of centres is so inadequate that for the majority of sufferers no facilities for appropriate treatment are available. By careful husbanding, the total funds at the disposal of the Council have increased to nearly £9,000.

CONSULTATION BETWEEN THE GOVERNMENT AND THE MEDICAL PROFESSION

The following statement has just been issued by the Secretary of the British Medical Association:

This announcement is of importance to every member of the medical profession. It was made clear on behalf of the Government in the recent Parliamentary debate on the Beveridge report that the object of the Government is to organize publicly for the first time a unified and comprehensive health service to cover the whole range of medical service, special and general, institutional and domiciliary, this service to be universally available to every member of the community.

At the Minister of Health's invitation representatives of the main bodies of the medical profession, including the British Medical Association, met him on Tuesday, March 9, to consider his suggestions on the procedure to be adopted for consultation between the Minister and the medical profession in the months ahead. The Minister has asked that there shall be set up a committee, representative of the medical profession as a whole, to consider with him and his officers the many and important problems and difficulties involved. It was agreed that this committee would have no power whatever to commit the medical profession either in principle or in detail. Further, an undertaking has been given that the discussions will take place not on the basis of any preconceived plan of the Minister, but "from the ground." It is contemplated that when the stage is reached that the Government, after consultation with the medical profession, is ready to indicate in general terms the measures the Minister has in mind to submit to Parliament on behalf of the Government, those proposals will be submitted, before any final decision is reached as to what is to be put before Parliament, to the various medical bodies represented in the discussion with the Minister, for their full consideration and the expression of their views.

In the case of the British Medical Association this will mean that at the appropriate time the Government's provisional proposals will be considered by the Council and all Association Committees affected, including Group Committees, by the Divisions, and by the Representative Body. Divisions will be requested to ascertain the views of non-members as well as members of the Association. After decision by the Representative Body, and only then, will the Association be asked to commit itself to decisions. Similar considerations apply to the other co-operating medical bodies.

The Minister's assurance is set out in the following official communication addressed by the Secretary of the Ministry of Health to the Secretary of the British Medical Association:

"Dear Dr. Anderson,

"Following the preliminary meeting which took place on Tuesday last between the Minister and representatives of the medical profession it may be useful if I set out shortly what we conceive to be the scope and purpose of the discussions of the proposed National Health Service which, as has been agreed, will now take place.

"I need not tell you that the establishment of a Health Service on the lines envisaged by the Government would constitute the greatest single step forward in public health in the history of this country, nor that the working out of this scheme will throw up a mass of novel and difficult problems. Moreover, the scheme will of necessity affect deeply the structure of the medical profession. These considerations alone would make it incumbent on the Minister and his advisers to seek all possible help and guidance from the profession; and, so far as the Department is concerned, this is the primary object of the proposed discussions.

"The Minister appreciates, of course, that views expressed on your side must not be taken as committing the profession as a whole, and similarly he does not contemplate announcing in the course of the discussions any final conclusions on the part of the Government. What he desires is a frank expression of the opinions of those best qualified to judge both issues of a technical and professional kind and—what is no less important—as to the probable attitude of the profession towards any proposals that may be put forward.

"We contemplate that at some stage it will no doubt be convenient to the profession, and, indeed, to all concerned, if a statement is published indicating in general terms the kind of measures which the Minister would have in mind to submit to Parliament on behalf of the Government. This will afford your group ample opportunity for further deliberation and reference back to the constituent bodies; and in framing any time-table we shall not lose sight of the fact that so many of the profession are serving over-seas

"As you will understand, the same considerations will apply to the discussions now about to begin with representatives of the local government organizations and of the voluntary hospitals.

"I am authorized to say that the Secretary of State for Scotland has seen this letter and agrees that its terms represent the basis on which any discussions which may take place with the profession on problems that have special reference to Scotland will proceed.

"I may add that you are at liberty to bring this letter to the notice of the profession by publication in the medical press or otherwise as you think fit.

"Yours sincerely,

(*Signed*) E. J. MAUDE"

Consultations have been proceeding between the Association, the three Royal Colleges, and the Society of Medical Officers of Health as to the composition of the representative committee to take part, though not as plenipotentiaries, in the discussions with the Minister and his officers on the position in England and Wales. It is anticipated that the general discussions on the main fabric of the proposed scheme will cover Scotland, and for this purpose special representatives of Scotland are added. It has been agreed that a body of the following composition can be regarded, for the purposes of these discussions, as adequately and properly representing the medical profession The Representative Body of the Association at its meeting on March 31 will be asked to endorse this view.

Representative Committee

Chairman of Council of B.M.A. (Mr. H. S. SOUTTAR).
Chairman of Representative Body of B.M.A. (Dr. PETER MACDONALD).
2 representatives of Royal College of Physicians: Lord MORAN, President; Dr. H. E. A. BOLDERO.
2 representatives of Royal College of Surgeons: Sir ALFRED WEBB-JOHNSON, President; Sir GIRLING BALL.
2 representatives of Royal College of Obstetricians and Gynaecologists: Sir WILLIAM FLETCHER SHAW, President; Mr. W. GILLIATT.
2 representatives of Society of Medical Officers of Health: Dr G. F. BUCHAN; Dr. H. M. C. MACAULAY.
2 representatives of Medical Women's Federation: Dr. DORIS ODLUM; Dr. MARY ESSLEMONT*.
1 representative of Provincial Teaching Staffs Association: Prof. T. H. OLIVER.
Chairman of Conference of Local Medical and Panel Committees (Dr. J. A. BROWN*).
Prof. R. M. F. PICKEN, Chairman of Public Health Committee, B.M.A.; Professor of Preventive Medicine, Welsh National School of Medicine.
Mr. R. L. NEWELL, Chairman of Hospitals Committee, B.M.A.; Hon. Assistant Surgeon, Manchester Royal Infirmary.
Prof. HARRY PLATT, member, Special Practice Committee, B.M.A.; Professor of Orthopaedic Surgery, University of Manchester.
Prof. HENRY COHEN, Professor of Medicine, University of Liverpool.
Dr. H. GUY DAIN,* Member of Council and former Chairman of Representative Body, B.M.A.
Dr. E. A. GREGG,* Chairman of Insurance Acts Committee, B.M.A.
Dr. S. WAND,* Chairman of General Practice Committee, B.M.A
Dr. A. S. WIGFIELD,* Hon. Secretary, East Herts Division; Physician, Royston Cottage Hospital.
Dr. S. A. WINSTANLEY,* Member of Insurance Acts Committee, B.M.A.; Hon. Medical Officer, Urmston Cottage Hospital.
Dr. F. GRAY,* Member of Council and of Insurance Acts Committee, B.M.A.
Dr. P. V. ANDERSON,* Member of Insurance Acts Committee, B.M.A.; Hon. Secretary, Bishop Auckland Division.
Dr. O. C. CARTER,* Member of Council, B.M.A.; Hon. Secretary, Bournemouth Division; Hon. Anaesthetist, Royal Victoria Hospital, Bournemouth.
Dr. D. J. B. WILSON,* Member of Insurance Acts Committee, B.M.A.; Chairman, Buckinghamshire Division.
Dr. J. A. L. VAUGHAN JONES,* Member of Council, B.M.A.; Hon. Secretary, Leeds Division.
Dr. A. TALBOT ROGERS,* Member of Insurance Acts Committee, B.M.A.; Hon. Medical Officer, Bromley and District Hospital
Dr. W. V. HOWELLS,* Hon. Anaesthetist, Swansea Hospital.
To be appointed: One Member of Staff of Provincial Non-teaching Hospital.

Scottish Representatives

Royal College of Physicians, Edinburgh: Prof. C. MCNEIL, President.
Royal College of Surgeons, Edinburgh: Mr. H. WADE, former President.
Royal Faculty of Physicians and Surgeons, Glasgow: Dr. J. H MACDONALD, President.
Dr. J. B. MILLER,* Deputy Chairman of Representative Body, B.M.A.
Dr. A. F. WILKIE MILLAR,* Chairman of Scottish Committee, B.M.A.
Dr. J. F. LAMBIE,* Chairman of Scottish Insurance Acts Subcommittee, B.M.A.

---

* General practitioner.

The B.M.A. fully recognizes that so far as is possible every step should be taken to give members of the profession on Service an opportunity of expressing their views on any plan put forward by the Government. When proposals are put forward by the Government for examination by the medical profession, machinery will be set in motion for communicating individually with Service men and women whose views cannot be ascertained through the normal machinery, for the assessment of those views, and for their presentation to the Representative Body.

Now, as perhaps never before, there is a need for unity within the medical profession. The present phase is one of consultation without commitment, and the various bodies within the profession, notably the B.M.A. and the Royal Colleges, have agreed to co-operate in one representative committee. It is inevitable that any scheme of reorganization deeply affecting the structure of the medical profession should be the subject of discussion, difference, and controversy. What is necessary now is that the medical profession should have confidence in those who will represent them in preliminary discussion, awaiting the time when, through its own organizations, it can examine concrete proposals and express its considered views.

Correspondence

The Need for a National Accident Policy

SIR,—The Factory and Welfare Advisory Board of the Ministry of Labour and National Service have recently published a pamphlet (PL113/1942, December, 1942) entitled "Fracture Treatment and Rehabilitation—Emergency Hospital Scheme." The Board state that they "are anxious that industrial workers who, *because of accidents of any kind*, may be in need of special treatment should be in a position to take advantage of all the facilities that may be available for the provision of this treatment." And then they state that "for this purpose . . . employers, trades unions, personnel management, and other interested persons should be aware of the facilities that have been provided under the Emergency Hospital Scheme by the Ministry of Health and the Department of Health for Scotland for fracture treatment and rehabilitation of industrial workers." The pamphlet goes on to show how this scheme has developed from one originally "intended mainly to cope with air-raid needs and to help the Services" to one which includes "a large-scale orthopaedic and fracture treatment service, with facilities for up-to-date rehabilitation" for "war industry in the widest sense, including munition work, ship building and repairing, building and civil engineering, mining, agriculture, fishing, public utility undertaking, shipping and transport." This "service" applies whether the fracture occurs during employment or not.

So far so good, but when men and women are injured in factories only a small proportion of those cases which lose three days or more—i.e., reportable accidents—are fractures. Evidence for this statement comes from the Annual Report of H.M. Chief Inspector of Factories (1936), where it is stated that 8,530 fractures occurred, excluding fractures of the skull, out of a total number of 176,390 injuries—i.e., a fracture incidence of 4.8% in a factory population then of over 5,000,000. Even if the rate for 1942 is greater it is reasonable to suppose that it is still below 10%.

In a covering letter introducing his policy for fracture treatment which he sent to the director of the British Employers' Confederation on Dec. 28, 1942, Mr. Ernest Bevin states that the purpose of this arrangement—namely, the fracture treatment service, including rehabilitation—was "to get those employed in industries vital to the war effort back to their posts at the earliest possible moment and as fit and well as modern medicine could make them." We must agree that fractures require specialized treatment by specially trained surgeons, and in industry we are more than grateful that this view is at last generally accepted by British surgeons, thanks to the pioneer work of the B.M.A. Fracture Committee. But from the evidence it is reasonable to suggest that Mr. Bevin's Advisory Board and Mr. Bevin himself have not faced the problem fully. Why only provide special facilities for fractures, which constitute at most one-tenth of the cases? Is the reason possibly the fact that Mr. Bevin is inadequately advised? I feel certain, from personal knowledge of the vigorous action that he has taken in other matters to do with the health of the working man, that if the position was laid fully before him he would act still more forcefully and introduce a scheme to include all workers who are incapacitated because of accident, no matter what the form.

So once again British surgery has a challenge, this time directly from the workers themselves, through those of us who are in daily contact with them in the factory. They demand that the treatment and rehabilitation of the soft-tissue injury, the infected hand, or the lacerated wound will be on a par with that available for the fracture. For these injuries, both in their effect on production and on future earning power, are in every way as incapacitating as the fracture; and because numerically they outnumber fractures many times, the problem they present is proportionately greater. Who, then, is to take up this challenge? Will the British Orthopaedic Association come into the field and give us a lead? It seems to me that orthopaedic surgeons, and in particular those who come into personal contact with injured members of the fighting Forces, must surely be the body not only best organized but as a group most fully qualified to provide the answer.—I am, etc.,

Birmingham DONALD STEWART.

Blood pH and Haemolysis

SIR,—Lieut.-Col. Felix Smith and Capt. R. Winston Evans (March 6, p. 279) appear to make two claims: (1) that increasing the *p*H of hypotonic saline increases the resistance *in vitro* of erythrocytes from normal and malarial subjects to haemolysis in that solution; and (2) that increasing the *p*H of the blood *in vitro* increases the resistance of the erythrocytes of blackwater fever patients to haemolysis in the blood stream. That they regard these two observations as related is shown by their statement: "The application of the results of the experimental work on fragility mentioned above is obvious. Alkalis must be given in such amounts as actually to increase the *p*H of the blood plasma." With a similar argument one could say that because oxygen will relieve an airman at 15,000 ft. of his light-headedness and irresponsibility, therefore it will cure the drunken sailor at sea level of his alcoholic intoxication.

It is true that in some, but not all, haemolytic states there is an increased osmotic fragility of the erythrocytes. This is, however, much more likely to be a result rather than a cause of the disease process. Even in familial acholuric jaundice, where the change is marked, the condition persists after splenectomy when the haemolysis is checked. And in blackwater fever the fragility is only very slightly increased.

It would be more reasonable for the authors to claim that alkalinization of the urine in blackwater fever cases is not sufficient and that a state of alkalosis must be produced to prevent haemolysis, though to do so would need more evidence than they have brought forward (their observation is apparently based on the findings in three out of their sixteen cases). To relate this, however, directly to the prevention of haemolysis *in vitro* under highly artificial conditions is unwarrantable. Furthermore, while none of the dangers of alkalosis has been mentioned, treatment by early blood transfusion is deprecated, in part because of the alleged but not substantiated high reaction rate. This is attributed to incompatibility of the donors' blood, so that a cross-matching test at ice-box temperature is recommended. "It often happens that out of a dozen donors, all of the same group as the patient, only one or two—and sometimes none at all—are really compatible when subjected to this stringent test." The authors cannot be aware of the fact that 75 to 98% (according to various authors) of normal bloods contain auto-agglutinins active at this temperature. Thus under the conditions laid down the vast majority of donors would be incompatible even with a normal recipient. It would be more logical to advise cross-matching at 37° C.; auto-agglutinins active at room temperature but not at body temperature are not infrequently found in haemolytic states. Pseudo-agglutination also is often extreme.

One's experience of cases of blackwater fever in this country is necessarily limited. In two recent cases, however, repeated blood transfusions with concentrated red cell suspensions were without reaction and gave most satisfactory results. Similar good results have been obtained elsewhere. This may largely be due to the extreme care taken by the War Emergency Blood Transfusion Services in the preparation of anticoagulant solutions and administration apparatus. Certainly one would require evidence that (*a*) pyrogens were absent from the authors' transfusion fluids and apparatus, and (*b*) reactions were unduly common and severe in cases of blackwater fever, but not in control cases, before denying such patients the generally accepted benefits of blood transfusion.—I am, etc.,

Sutton, Surrey. JOHN F. LOUTIT.

Calorie Control

SIR,—The article by Dr. A. C. Crooke and Miss Ella Scott (Jan. 16, p. 64) and the comments thereon are most instructive. I am sure Dr. Crooke is right, and I believe that Dr. C. M. Fletcher's observation (Feb. 13, p. 201) that diabetics (he might have said all Englishmen) are conservative in their dietary habits is part of the explanation. The limits within which reasonable meals can be altered are small. For the purpose of this controversy a diabetic, taking a daily morning dose of Z.P.I. 28 units and S.I. 12 units, has made a great effort to vary the proportion of carbohydrate in a breakfast of 500 calories. The results are tabulated below:

Day	C.	P.	F.	Calories	B. Sugar in mg.%		Result	Remarks
					8 a.m.	12 noon		
1	55	22	23	515	300	225	Drop 75 mg.%	Ordinary breakfast
2	75	20	13	497	343	131	Drop 212 mg.%	High C.
3	37	33	26	514	112	162	Rise 50 mg.%	Low C.
4	80	20	13	517	93	93	No change	High C.
5	34	22	32	512	93	93	No change	Low C.
6	83	18	10	494	68	Insulin reaction	Drop	Severe insulin attack 11.30 a.m.–1 p.m.
7	37	22	30	506	306	281	Drop 25 mg.%	Low. C.

The meals fall into three groups according to the amount of carbohydrate. First, the usual type of breakfast with 55 g. C.; secondly, three with 75 g. C. and over; and, thirdly, three with 37 g. C. and under. The protein was fairly constant (18 to 33 g.) and the fat varied from 10 to 30 g. The food value varied only by about 20 calories.

As judged by the fall in blood sugar the insulin had a greater effect when the proportion of carbohydrate was high; indeed a severe insulin reaction occurred 3½ hours after the highest carbohydrate breakfast. The reason is, perhaps the rapid digestion and absorption of carbohydrate which in the presence of insulin is withdrawn from the blood and stored.

So far as they go these results confirm Dr. Crooke's contention that carbohydrate, protein, and fat can be interchanged. This principle is not new. Ten years ago Rabinowitch (*Diabetes Mellitus*, Toronto, 1933) used a high-carbohydrate, low-calorie, and, especially, low-fat diet (e.g., 238 C., 80 P., 90 F.), and claimed that less rather than more insulin was needed than with the high-protein and fat diets usual at that time (e.g., 80 C., 100 P., 150–200 F.). Both he and Dr. Crooke recognize a constant calorie value as the steadying factor, and Dr. Crooke has gone a step further in varying the ingredients which make up the total calories. He has done a good service to all diabetics in removing almost the last difference between them and normal people.—I am, etc.,

Hove G. M WAUCHOPE.

Caesarean Section in Dystocia

SIR,—I am substantially in agreement with the views expressed by Mr. L. G. Higgins (Feb. 20, p. 212). The points I wish to raise are merely minor criticisms and do not affect my sympathy with his main proposition that Caesarean section is less dangerous for the mother and child than difficult vaginal delivery.

The series of cases which he gives in support of his thesis at the top of page 213—868 with 3 deaths—includes 318 reported by individual operators without mortality. The trouble is that individual operators tend to report series only when the mortality is notably low. What is required to get an accurate idea of the mortality of the operation is an inquiry on the lines of that made by Holland and Kerr in 1921, covering all the large maternity units in Great Britain. This would eliminate the element of luck and demonstrate the results of the operation in average skilled hands.

It is not quite clear whether Mr. Higgins's paragraph on elective operations applies to the lower segment operation only; he does not actually say so.

Later on, when considering the maternal mortality of forceps delivery, he picks on two unnamed hospitals whose figures he gives, and deduces that the mortality is about 1%. We are not told anything about the state of these mothers. Is it not fair to suggest, as he himself does higher up about Caesarean section, that in some of these forceps cases the mother may have been "suffering from some grave complication, by which the outlook is already prejudiced." While I am convinced that his main proposition is right, it does not seem to me reasonable to compare a largely selected series of Caesarean sections with an unselected series of forceps deliveries from two hospitals.

Any extensive survey of the results of Caesarean section in Great Britain should certainly include figures on rupture of the lower segment scar. It is frequently stated that the risk is very small, and this is probably true, but it would be much more satisfactory to have a large body of statistics on the subject. Surgeons do not always publish their cases of ruptured scar, and the experience of a single hospital, even a very large unit, is not great. The lower segment operation, as Mr. Higgins points out, has revolutionized the outlook for potentially infected cases, and I hope we have now left far behind us the days when every Caesarean section was regarded as a blot on the hospital statistics. Our aim should be to get the best possible results for mother and baby in each case, whatever method is used. This paper goes far to show the advantages of Caesarean section in cases other than the older indications of severe contraction of the pelvis and pelvic tumours.—I am, etc.,

Leeds. ANDREW M. CLAYE.

Scientific Freedom and Social Medicine

SIR,—I thought the suggestions made by Dr. Geoffrey Bourne (Feb. 20, p. 227) were excellent so far as they went. They do, however, fall a little short of the changes really necessary. I have no doubt that Dr. Bourne had in his mind concerning the voluntary hospital a continuance of the present medical representation on the governing board, but he does not propose any extension of the arrangement to the public health hospital. Personally I would go further. In my view the present method of running hospitals by lay committees with a somewhat sparse sprinkling of medical members is not the best conceivable. I would like to see the board or committee responsible for the immediate running of each hospital, voluntary or public health, very radically changed to allow the staffs a much greater power in the control. I do not, of course, suggest any change in the ultimate control of public health hospitals by the duly and democratically elected local authority.

My standard board for both sections of the hospital world would consist of three groups of members. First, representatives of local citizens—i.e., members elected by the subscribers in voluntary hospitals and nominated by the local authority in the others. This group could, of course, be increased within limits by the co-option of people interested in and useful to the hospital. Secondly, representatives of the medical staff to a number at least equal to group 1. Thirdly, representatives of various outside bodies. These might include representatives nominated (*a*) by the local general practitioners, (*b*) by the Ministry of Health through some local organization, (*c*) on voluntary hospitals by the local public health authority, and on public health hospitals by the neighbouring teaching or important voluntary hospital, (*d*) by possibly the B.M.A. This third group would be chiefly liaison in function, but would doubtless provide a volume of valuable knowledge and experience. It would also serve to keep the balance between the first two groups.

I am afraid that, unless the public is made aware of the views of the profession by a vigorous campaign, there is very little hope of any reform in the present unsatisfactory methods of running many of our hospitals. In this country the quickest and best method of obtaining results in such a matter is by those most interested getting together and working to the same end—in other words, by forming a committee or society. I am sure that a man in Dr. Bourne's position would have no difficulty in calling such a committee into being if he desires to do so.—I am, etc.,

London, S.W.20. A. J. HOBSON.

SIR,—Dr. Geoffrey Bourne (Feb. 20, p. 227) has done well to reiterate the importance of scientific freedom, Sir James Walton (March 6, p. 298) to point out how much of this freedom is a keynote of the Medical Planning Commission's draft interim report. Freedom, however, like so much else in the world to-day, is total. Security, for instance, is national and social. Each aspect in some respects enhances, in some restricts, the other. The components of freedom are scientific, spiritual, social, economic, and so on, each reacting as above on the rest. Many to-day, rightly or wrongly, put economic before spiritual or scientific freedom. There is one way, perhaps, by which economic freedom might be used to support scientific freedom so far as doctors are concerned.

The profession might be organized in various services—e.g., a national service of general practitioners; a regional service of voluntary hospital doctors (and perhaps other hospital doctors); a local authority service of public health doctors; a Royal Naval, a Royal Army, a Royal Air Force, perhaps a Mercantile Marine Medical Service, and so on. The doctor in each could be given a basic salary according to his years of postgraduate work, plus emoluments. The basic salary could be the same in all services, irrespective of rank, if any, for a doctor of the same postgraduate experience, no matter in which service or services that experience had been gained. The emoluments would, of course, vary. Thus in the fighting Services there could be emoluments in respect of rank. General practitioners could be paid a fee for emoluments according to the number of persons or scores or hundreds of persons on their list. (Administratively, according to some authorities, a unitary capitation system applicable to the whole population is impossible.) Hospital doctors could have their basic salaries augmented according to whether paying or insured persons could be seen or attended inside or outside the hospital. Similarly, stated emoluments could be paid to local authority doctors. All emoluments, or the principle underlying the payment of emoluments, should be frankly disclosed, however.

A system of equivalent basic salaries such as this might emphasize equality and scientific freedom among doctors; it would also make for mobility. Thus the young practitioner would not require to decide unduly early the service to which he proposed to devote his life-work. He could take his seniority (qualification for increased basic salary) with him wherever he went, and in wartime practitioners could be transferred to the fighting Services with less hardship than at present.—I am, etc.,

Glasgow J. INGLIS CAMERON.

The B.M.A. and the Beveridge Report

SIR,—Many of your correspondents on the free choice of doctor under the Beveridge scheme seem to take the attitude that "100% medical service" is a standard commodity that should be obtainable at the same price at every surgery. In practice, so much of medical therapeutics depends on that intangible quality "confidence" and so little on the actual drugs or technique employed that it seems to me essential for the welfare of the patient that within certain limits they should be allowed to pay their money and take their choice!

The field of medicine is so vast that no one practitioner can ever be equally good at everything. There will always be the man who has a "way with children," or special experience of skins, E.N.T., eyes, gynaecology, etc., and it should be possible for any patient to avail himself of these local subspecialties and for the practitioner to accept remuneration in exchange.—I am, etc.,

New Malden, Surrey HELEN LUKIS.

SIR,—There is one factor that your correspondents who favour the deletion of proviso (*b*) of the B.M.A. resolution have overlooked and that is, the point of view of the patient. The majority of those who can afford private fees would resent being placed on a "panel." Sir John Anderson recognized this fact in presenting the Government's view. He said, as reported in your columns: "The Government has no intention of forcing the new services on those who preferred to make private arrangements for medical attendance or hospital treatment."

There is a certain class to whom the benefits of the panel system might quite rightly be extended—i.e., the dependants of those within the present income limit. Under the present panel system all the benefits of the Beveridge report are available already. We send our patients to consultants at the hospital when necessary. By the hospital contributory scheme, which Sir William himself says is the ideal method, the patients benefit from all the hospital's resources. The tuberculosis clinic and the child welfare centre are open to all. Above this income limit, patients are prepared to pay for treatment and usually prefer to

The panel system, admirable as it is in many ways, rightly or wrongly leaves with the patient a suspicion of superficial treatment and with the doctor a sense of insufficient remuneration for services rendered. That feeling will not be eradicated by including the whole population in a similar system, however extensive a propaganda extolling its benefits might be undertaken. If wealthy patients by purchasing a paltry weekly stamp can command the unlimited services of a doctor, discontent and resentment cannot but arise. They themselves would not wish to be in the same medical category as their household staff.—I am, etc.,

Histon, Cambs A. E. MOORE.

SIR,—Some of us, surely, will hardly agree that Dr. H. W. Bland (March 6, p. 299) has put a question which can blow "sky-high" item (*b*) of the forthcoming motion before the Representative Meeting. Provided the medical profession offers to "every man, woman, and child the whole resources of modern medicine," such private patients could expect no advantage from their doctor. They might like, however, to preserve the priceless capacity of independence in much the same way as any individual may hitherto (in peace) secure his source of power and light privately and not through a public utility service. Moreover, in such case, these potential private patients will confer on the medical profession a degree of independence which many doctors, I feel, value highly.

This is, in my view, a potent argument in favour of item (*b*); but coupled with this it should be categorically stated that the whole "resources of modern medicine" will not be available to anyone unless the remuneration of the services of consultant and general practitioners is properly assessed, and item (*b*) should, therefore, not be taken into account by the negotiators in a fractional sense in the terms of service.

Allied to this aspect of the case is Dr. Geoffrey Bourne's plea for "scientific freedom," more especially with reference to hospitals. The late Mr. Wilfred Trotter spoke of the pursuit of the "dying ideal that an occupation for adults should allow of intellectual freedom." We hope such freedom will be amply allowed to the medical profession, outside as well as inside hospitals, in any scheme which is formulated.—I am, etc.,

St Albans D. S. MORGAN JONES

SIR,—In view of the fact that the most important conferences are shortly to be held at B.M.A. House to decide the attitude of the profession towards the medical side of the Beveridge report, I suggest that it would be well if both delegates and those whom they represent should endeavour first to find the answers to the two following questions.

First, why is it necessary at all to link up the reorganization of the medical profession with a "security from want" campaign? For many years now provision has been made for skilled medical attention for all classes of the community by panel practice, public medical services, school medical services and clinics, maternity and child welfare clinics, hospital and pathological services, and so on. Where, then, does a new scheme of freedom from want of medical service find scope for improvement? Secondly, why is it so necessary to hurry the medical side of the scheme when the remainder of the report is to wait until after the war is over? It is evident that the Minister of Health is in some haste, for he has already summoned certain members of the profession before him to hear his views.

I suggest that there is the same answer to both questions—namely, it is entirely a political matter, perhaps even a party political matter. This war, unlike most wars, is between two rival ideologies: the one, that of the Axis Powers, stands for State organization of the whole nation, or perhaps of every nation; the other, that of the democracies, stands for individualism in effort, in ambition, in freedom, and in reward, upon which the democratic idea is founded. The fact that

Russia is an ally does not affect the issue, because Russia is fighting for her own survival and did not join the democracies until her own safety was attacked. The struggle of the two ideologies, of which this war is a high-spot, has been going on for forty years, and will not be over even when the democracies have won, for it now appears that the planners of State organization, both in Parliament and among our own ranks, are preparing, as they put it, "to win the peace" for their own ideology, which is not that of democracy.

The first tactical move has already been made in this attack on one of the strongholds of individualism—the medical profession—and it is well camouflaged by hanging the proposal on to a general scheme of social insurance for all. But the ultimate purpose is revealed, partly by the haste to put it through during a party truce and during the absence on war service of many who will be vitally affected, while the rest of the report is to be postponed until after the war; and partly by the demand that by this scheme to include everyone, rich and poor alike, it is not really designed to advance "freedom from want" so much as to absorb the entire means of livelihood and the capital invested in their practices of the whole profession, and thus bring this proud and independent body of men under the complete control of the Minister of Health.

I trust, Sir, that the delegates, refusing to be influenced by the doctrine of defeatism so freely preached in some quarters, and realizing that the eyes of the country as well as the profession are upon them, will consider this point of view before taking the enormous responsibility of making such a surrender to the planners of State organization.—I am, etc.,

Diss, Norfolk. J. CUTHBERT PEARCE.

Dietetics of Pregnancy

SIR,—Dr. Doyne Bell's excursion into the field of statistics (March 6, p. 301) and his attempt to show that the "results of the work sponsored by the P.L.H. had no significance" have been dealt with by the statistical members of the committee responsible for the investigation (Feb. 13, p. 204; March 6, p. 301). We must leave your readers to determine how far Dr. Doyne Bell is entitled to enjoy his comforting conclusion that "there is no point at issue between us."

As chairman of the People's League of Health Committee on Maternal Nutrition I would again reaffirm the importance we attach to the significant reduction in prematurity achieved by the administration of nutritive supplements in a research involving about 5,000 pregnant women. These results are reinforced by the work of Toverud in Norway and the investigations carried out in Toronto, and by the well-established observations of the animal breeder.—I am, etc.,

London, W.12. JAMES YOUNG.

SIR,—I have been following the correspondence on this subject initiated by Mr. R. B. Fisher (Jan. 30, p. 144), but there appear to be still one or two points with regard to the Canadian experiment which have been overlooked.

In assessing the value of an experiment from the reported results it seems important to discover as far as possible what the experimenters did in fact do, and to judge the adequacy of the experiment on these grounds rather than on any minor numerical inconsistencies in the report itself. Had Mr. Fisher adopted this approach he would immediately have resolved what he describes as "a puzzling and unsettling phenomenon" —namely, that some of the percentages when multiplied by the stated numbers in the groups do not give whole numbers. It can easily be deduced that for the poor and supplemented groups the numbers on which the percentages giving the obstetrician's ratings were based (in the pre-natal period and during labour) were not 120 and 90 but 116 and 87. Other percentages in the tables present more difficulties, but there seems no reason to doubt that the report as a whole gives a reasonably correct statement of what was observed.

The real difficulty, which none of your correspondents seems to have commented on, is the difference in numbers between the poor group (116) and the supplemented group (87). It is stated that "in those with a poor diet and a low income alternate patients were left on their poor diet," the remainder being given supplements. If the poor and supplemented groups were really selected in this manner occasional rejections for extraneous causes could not give rise to a difference of this magnitude.

A statement by Dr. Doyne Bell in the report referred to by Mr. Fisher may explain the difference. He says: "The general scheme of this work was to study the performances in childbearing of two groups of mothers, one on a 'poor diet' and the other on a 'good diet.' It was soon appreciated that these two groups were not comparable, so the 'poor diet' group was divided into two, one of which had the diet supplemented to the standard of the original 'good diet' group." I have been unable to find any confirmation of this in the published accounts of the experiment, but if true it would lead to a greater number in the poor-diet group. If this is the case these preliminary patients should have been eliminated from the tables giving comparisons between the poor and supplemented groups, since they may not be strictly comparable with the later patients, and the obstetrician's ratings may also have changed as the experiment progressed.

Incidentally, it may be mentioned that Dr. Bell's conclusion (based on the previous histories of the multiparae) that the two groups, poor and supplemented, "differ so widely that neither constitutes a control series of the other" is entirely without foundation. If the percentages he quotes are translated into actual numbers, statistical tests show that differences of this magnitude may be expected to arise by chance.

The large number of miscarriages occurring in the poor-diet group may also be an indication of defective procedure. As Prof. John Marrack has pointed out (Feb. 27, p. 268), miscarriage probably covers all births up to the 28th week of pregnancy; but even so it is rather surprising that the supplementary feeding, which was only begun in the 5th or 6th month, produced such a considerable difference. From the report it is clear that the patients were under observation for a week in order to decide whether they were to be classified as falling in the poor-diet or good-diet group. Another week probably elapsed before supplementary feeding commenced. It is possible that if a miscarriage to a poor-diet patient occurred in this period she would be included in the poor-diet group. This would give a valid comparison with the good-diet group, but an obviously invalid one with the supplemented-diet group. Even assuming that all the seven miscarriages in the poor group occurred in this way, and that they received poor or bad ratings by the obstetrician, their elimination would still leave very significant differences between the poor and supplemented groups. The experiment has obviously been carried out with considerable care, and it does appear on the face of it, in spite of the efforts that have been made to cast doubt on the results, that a considerable effect of diet improvement has been shown.

Further speculation, however, is obviously unprofitable. It would surely be more reasonable if the original authors were approached directly in order that the difficulties and objections that have been raised can be resolved. I cannot believe that they would be unwilling to furnish more detailed results.—I am, etc.,

Rothamsted Experimental Station. F. YATES.

Treatment of Fulminating Meningococcal Septicaemia

SIR,—Although Dr. S. Varadi (Nov. 28, p. 649) and every physician must regard fulminating meningococcal septicaemia with dismay, it is not to be supposed that such a condition is beyond the healing influence of sulphapyridine, even when complicated by bacterial emboli. "The proof of the highest efficiency of chemotherapy" is demonstrated in the following case history.

An able seaman aged 20 reported in the sick-bay of our ship at 15.30 on April 28 because of a sore throat and headache of four hours' duration. He had left his post, finding the concussion of the 4.7-in. guns unduly disturbing. Before his history was completely told the patient vomited clear fluid and collapsed. A few minutes later, complaining bitterly of his headache, and vomiting effortlessly, he sank into an ingravescent coma. Within twenty minutes of his first appearance he seemed at the point of death, flaccid though restless, cold, clammy, and grey, and heedless of the most urgent stimuli; pulse palpable only in the neck, rate 125; temperature 97° F. and falling; respirations 25. He lacked specific physical signs except slight nuchal rigidity, but the natural history suggested either fulminating meningococcal infection, subarachnoid haemorrhage, or poisoning.

A lumbar puncture at 16.00 tapped ground-glass grey fluid at low pressure, containing about 80 cells per 1/6th field, and Gram staining revealed Gram-negative diplococci in many of the pus cells. At

16.05 a purpuric rash appeared and spread upwards from his legs. At 16.30, when he seemed moribund, one gramme of sulphapyridine sodium was injected intravenously. Two hours later he had improved constitutionally and the injection was repeated. By 19.30, when the purpura was diffuse and generalized, his state of shock was abating and he began to recover mental awareness. Meantime, general measures to aid him were taken, and had a supply of adrenal cortical extract been at hand he would have been given it, for he was certainly displaying the Waterhouse-Friderichsen syndrome.

It became necessary to transfer him from the warship, and chemotherapy was continued orally in one of H.M. hospital ships, where his recovery became complete. Fortunately this case was solitary, but it is reassuring to know that Banks's encephalitic form of fulminating meningococcal septicaemia is not an irreversible process, even in a battleship, if it is diagnosed immediately and treated promptly with sulphapyridine. We are indebted to the squadron medical officer, Surg. Cmdr. Gaussen, for permission to forward this note.

—We are, etc.,

J. N. MORRISON.
P. W. HOUGHTON.

The Pitressin Diagnosis of Idiopathic Epilepsy

SIR,—As Dr. W. Blyth (Jan. 23, p. 100) points out in his interesting article about pitressin diagnosis of idiopathic epilepsy, the method depends on the fact that retention of water in the body will precipitate a seizure in predisposed persons. This agrees with investigations about the metabolism of water and salt in cachectic, feverish, and epileptic patients which I carried out many years ago. In a good many cases of epilepsy I was able to predict the fit owing to the increasing water retention during the previous days. In all cases I observed a definite parallelism between the retention of water and NaCl, while other metabolites—e.g., phosphates or urea—were not retained.

I thus inferred that not only water retention but also chloride retention might be essential factors to precipitate epileptic seizures. In order to test this hypothesis 10 to 20 g. NaCl were daily added to the diet of epileptics (without increasing the water ingestion), as a consequence of which fits occurred far more frequently than hitherto. At the same time it was observed that by increasing the NaCl supply water retention took place, and vice versa that water retention, produced by increasing water supply, was always accompanied by NaCl retention. Simultaneous analyses of the serum and other body fluids showed that their chloride content remained constant and so did their electric conductivity. This definite relation between water and salt retention may, among other things, be responsible for the preservation of the osmotic balance in the body, a fact which would not quite agree with Dr. Blyth's deduction that water retention, through lowering the osmotic pressure of the blood serum, should be the only factor precipitating the actual seizure.

May I add that in the progress of the above-mentioned metabolic research in epileptics I could prove that chlorides are substituted by bromides during the usual bromide treatment, and vice versa that chlorides are able to liberate bromides from the human body; on the latter fact an effective therapy of bromism was based, which is still in use. Similar considerations led me to the treatment of epilepsy with salt-free diet (later on known as the Richet-Toulouse method), which combined with small doses of anti-epileptic drugs, such as bromide, luminal, or prominal, produces remarkable results.—I am, etc.,

Cambridge

R. LAUDENHEIMER.

Starvation in Europe

SIR,—The letter of Prof. James Young (Feb. 27, p. 270), coming after the letters on the subject of starvation in Europe published in the *Journal* and the *Lancet*, and also following the appeal of the British Paediatric Association, shows that the British medical profession, conscious of its traditions, wishes to take an active part in this serious humanitarian as well as political problem.

So far as Greece is concerned, the position, unfortunately, is quite exceptional in severity. As the Greek Red Cross pointed out in various communications, it is not a question of undernutrition, fostering the development of tuberculosis and of other deficiency diseases, but of a widespread famine, comparable to the worst famines in history, which has already killed nearly 400,000 people out of sheer starvation. We have, unfortunately, ceased to trouble ourselves at the Greek Red Cross with the simple spread of tuberculosis and of deficiency diseases. The tragic pictures given in the papers by neutral correspondents who have been to Greece, particularly during the first days of 1942—the description of children dying in the streets of Athens from lack of food, being collected by lorries every morning, piled up like sardines, and thrown into a common grave—are only too true; and even now, although some relief has been sent, the conditions of mortality have not improved, because famine does not stop immediately when some food is sent. One of the Swedish captains of the mercy ships sent to Greece remarked after his last voyage, two months ago: "The only thing I can say is that we have on our short visit this time not seen people dying on the streets from lack of food, as was the case on our first journeys—but that is all."

The main part of Greece—that is, south of Olympus—produces practically no food because it is a country essentially of high mountains with only two small plains in Thessaly and Peloponnesus. Formerly, this country had to rely on food imported by sea because there are practically no overland communications. In peacetime food could be sent also from Macedonia and Thrace, which produce more food than the main part of Greece, and this was also sent by sea except for a small quantity overland. As the sea route has been closed since the occupation of Greece, the country was simply starved to death. Fortunately, thanks to the active initiative of the British Government and the British public, and to the efficient co-operation of the International Red Cross and the Swedish Red Cross, relief has been organized since April of last year. It seems to have stopped the deaths from pure starvation, but it has not stopped the terrible morbidity and mortality that accompany famine, and epidemics like malaria, falling upon this intensely undernourished population, threaten the extinction of the race. We have had a definite warning, particularly regarding malaria, from the International Red Cross.

All this means that much more has to be done. Great efforts should be directed towards the humanitarian work of the relief of Greek famine, and it is a happy omen to note the interest of the British medical profession in this problem.—I am, etc.,

London, W.1.

A. P. CAWADIAS.

A European Association of Clinical Pathologists

SIR,—It is proposed to form a European Association of Clinical Pathologists among the medically qualified men and women of the various nations of Europe now engaged in this country in any branch of medical laboratory work.

Clinical pathology, although itself a special branch, permeates and establishes contacts with all departments of medicine. Experience has shown those of us who are members that the meetings of the already existing Association of Clinical Pathologists in this country afford peculiarly fruitful occasions for the gathering together of practitioners in the different branches of medicine on a ground of common understanding and interest, and thus encouraging the growth of a spirit of fraternity and co-operation. Of the value of the presence of such a spirit among the representatives of the various European nations now sojourning in this country there can be no doubt. It is our hope that on their return to their homelands the members of the European Association may in due course initiate branches in their own countries, which will retain close touch with each other and with the Association of Clinical Pathologists in this country.

We believe that such a movement, quite apart from its obvious advantage to medical science, would serve to encourage a feeling of accord and comradeship between the European medical communities, and thus make a contribution, small perhaps but by no means negligible, to international amity. We have every reason to believe that the Association of Clinical Pathologists, although it has not yet officially discussed the project, would do all in its power to assist, and that it would welcome the members of the proposed European Association to its meetings and to an active part in its proceedings.

A meeting for the purpose of discussing the matter and, if deemed advisable, of inaugurating the European Association will, by courtesy of the Dean of the Medical School, be held at University College Hospital, London, on Saturday, April 3, at 2 p.m. All medical practitioners from the Continent of Europe and from Great Britain alike engaged in any form of medical laboratory work will be very welcome. Those who feel interested are invited to communicate with Dr. F. Pick, Department of Clinical Pathology, the General Hospital, Walsall. Those who propose to attend are requested to notify Dr. Pick to that effect.—We are, etc.,

Foot-and-Mouth Disease in Man

SIR,—I was interested to read of the two cases of foot-and-mouth disease in man reported by Dr. Henryk Dlugosz (Feb. 13, p. 189). I had a case in a youth, aged 18, which started with small circumscribed areas of erythema in the mouth, on the gums, cheek, and hard and soft palates. These then formed into greyish-white vesicles with a thin serous fluid, finally bursting into shallow ulcers. He developed a temperature of 100° F. on the third day, and this persisted for four days. Similar lesions developed on the hands and feet, but only caused slight irritation. The dysphagia became less about the twelfth day and the hands and feet improved as well, but there was staining for about six weeks.

One interesting point was that he had had two previous attacks within three years, but they had only been very mild, thus showing that he had no lasting immunity. This youth was a clerk and so was not exposed to contact with cattle, but he had been told to drink plenty of milk when he was a child, thus leading one to believe that this was a likely source of the infection.—I am, etc.,

Preston. G. S. PARKER.

Ward Sisters' Salaries

SIR,—At a recent meeting of the Middlesex County Medical Society the recommendations of the Rushcliffe Committee on Nurses' Salaries were discussed. This society has a membership of approximately 200 doctors, most of whom are clinicians in the whole-time employment of the Middlesex County Council, and include the medical staffs of seven large general hospitals and two sanatoria, with a total bed accommodation of 8,472.

There was a unanimous feeling of dissatisfaction with the recommendations for the remuneration of ward sisters and its effect on their status. They consider an efficient ward sister to be a most important person in the satisfactory treatment of patients, in the training of the student nurses, and as an effective aid to the scientific advancement of medicine. These facts will be readily agreed by all who have an intimate knowledge of hospital practice, and it was regarded as deplorable that no ward sister was a member of the Rushcliffe Committee. The deliberations of the committee were felt to be influenced by the undue representation of the administrative hospital staff. It seemed obvious to the society that the upper limit of the ward sisters' salaries had been regulated so that in no instance should it exceed that of administrative sisters in small hospitals. This was felt to be quite unjustifiable.

It was suggested that the minimum salary scale of a ward sister should be that proposed by the committee of the Royal College of Nursing in 1941—i.e., £150 × £10 to £250 per annum, exclusive of emoluments. These emoluments should not be less than those of the administrative sisters, and they should be such as to encourage all trained staff to live outside the hospital. At present non-resident emoluments are based upon the cost of mass catering and accommodation in an institution. It should be quite obvious that no reasonable non-resident accommodation can be obtained at a comparable figure.

The society therefore wishes to place on record its dissatisfaction with the Rushcliffe Committee's recommendations, especially in regard to ward sisters. They feel it may deter the right type of girl from entering the nursing profession and prevent the good ward sister from looking upon ward work as a position of honour in the profession. They feel it will stabilize for years to come her position of inferiority and prevent that co-operation which is so necessary between the clinical and administrative sisters.—I am, etc.,

H. JOULES,
London, N.W.10. Chairman, Middlesex County Medical Society.

Obituary

The death of Dr. F. J. C. BLACKMORE towards the end of last year, at the age of 63, calls for a tribute to one who has left his mark on the antituberculosis service of the country. More than 20 years of his working life he spent as tuberculosis officer for Woolwich, a post from which he retired in April, 1940, on account of ill-health. He was secretary of the Woolwich Division from 1922 to 1925, and in 1923 and 1924 he represented his constituency at the Annual Representative Meeting. His dispensary work was distinguished by the special interest he took in the social welfare of his patients, who held him in very high regard. He was one of the first to develop occupational therapy for dispensary patients unfit for work, and he travelled widely to keep himself in touch with tuberculosis work in other countries. Dr. Blackmore was keenly interested in the wider problems of administration, and thereby became well known to his fellow workers throughout the country. He was a leading member of the Tuberculosis Society, of which he was honorary secretary in 1926 and 1927, and he was an original member of the Joint Tuberculosis Council, to which he rendered great service in studying and reporting on administrative questions. His best work, however, was done for the Tuberculosis Group of the Society of Medical Officers of Health, in which he held office as president. In discussion his outstanding characteristic was, in spite of an innate humility, his fearless honesty in seeking the truth and trying to express it. Those on whom his criticisms fell, at times like bludgeon blows, recognized his sincerity and the absence of personal feeling, and remained his friends. He leaves behind a widow and three sons, to whom the sympathy of a wide circle of fellow workers will be extended.

The city of Glasgow has lost by death a good many medical men recently, and one of the latest to die has been Dr. PETER S. BUCHANAN. Dr. Buchanan was a most keen and enthusiastic member of the B.M.A. for the past 42 years, and took a leading part in most of its agencies and was representative at the annual meetings during the years 1934 to 1939 inclusive; he was at the Aberdeen Meeting just before the outbreak of the present war. He was chairman of the Glasgow Eastern Division of the B.M.A. from 1927 to 1928. He developed an eye trouble which ultimately left him stone blind about two years ago, and he had to give up general practice. Latterly he had a bad fall in his home on account of his blindness, and fractured his pelvis, from the complications of which he died on Feb. 16 at the age of 72.

The district of Dennistoun and Townhead must feel his loss very much, as he had always a bright cheery smile and salutation when he entered a patient's house, and this made the opening interview a refreshing tonic in itself. Dr. Buchanan's father was a doctor for many years in the same district, and he must have learned many of his father's methods in the art of curing the sick. Their lasting rewards were the pleasure and enjoyment derived from the love of their profession, and the satisfaction of feeling the work was well and honestly done.—J. C.

JAMES MAIR STIRLING, whose untimely death on Feb. 7 has come as a shock to his many friends, was a native of Ayrshire. He was educated at the Technical College, Glasgow, and at Glasgow University, but the last war broke his studies and he joined the Border Regiment from the O.T.C. in 1914. Adjutant of his battalion for nearly two years, he later transferred to a Divisional Staff, and for his work in both grades he was mentioned in dispatches. Not the least notable years of an eventful life were the post-war early twenties. Prominent in any company, he was an outstanding member of the University of Glasgow, where he graduated B.Sc. in 1921 and M.B., Ch.B. in 1923. He was president of the Students' Representative Council and Secretary of the Union, and he played a large part in the Students' Welfare Scheme. After some years in the Western Infirmary and the city fever service he started in practice in the Levenshulme district of Manchester. Here he soon built up a good practice and made many friends, especially among his own profession. An intense individualist, scornful of pettiness and intolerant of sham, Stirling contended fiercely for the truth as he saw it. For him there were "no tricks in plain and simple faith"; but he knew how and when to be obstinate. He was loyal to his friends, magnanimous to an opponent, and when he espoused a cause, no matter how forlorn, he spent himself freely for it—perhaps too freely. At the time of his death he was a prominent and active member of the B.M.A., the Local Medical War Committee, and the Panel Committee, on all of which his common sense, logical viewpoint, and broad humanity had a powerful influence which will be sorely missed. His profession is poorer for his passing, but richer for his example.

The death occurred on Feb. 12 at St. Albans of Dr. G. B. BUCHANAN. George Burnside Buchanan was born into a medical family, his father being the first professor of clinical surgery at the University of Glasgow and at the Western Infirmary, Glasgow. He received his early education at Fettes College, Edinburgh, and then went to Cambridge, where he graduated B.A. in the Natural Sciences Tripos of 1890. Returning to Glasgow he took the M.B., C.M. in 1893. Dr. Buchanan travelled a good deal after he qualified, studying at the Universities of Marburg and Vienna, both of which centres were then attracting many postgraduate workers. He finished his foreign studies with a year in Paris, and returned to Glasgow, where from 1895 to 1899 he was assistant in his father's wards, and also helped the late Dr. J. C. Renton on occasion. He went with the British Army to South Africa in 1899 and was a civil surgeon throughout the Boer War, receiving the South African medal with two clasps. In 1901 he took the F.R.F.P.S. of Glasgow, and for the next ten years practised as a surgeon in that city. Endowed with a genial nature, Buchanan made many friends. He was secretary of the North-Western Division of the B.M.A. in Glasgow in 1908 and 1909, a division which included a very large number of the consulting medical and surgical staff attached to the University and to the leading hospitals. He served in the last war with the Scottish Horse, holding the rank of major, R.A.M.C.(T.). In 1911 he joined the staff of the Ministry of Pensions in London, and was Deputy Commissioner of Medical Services when he retired.

We regret to announce the death at the age of 66 of Dr. W. L. MURPHY, a well-known figure in the medical, commercial, and political life of Dublin. Son of the late William Martin Murphy, who founded the Independent group of newspapers in Dublin, he was himself chairman of Independent Newspapers, Limited. William Lombard Murphy was educated at Cambridge, Vienna, and Dublin. He qualified L.R.C.P.I. &L.M., L.R.C.S.I.&L.M. in 1904, taking the F.R.C.S.I. in 1906, the M.B., B.Ch. in 1907, and the M.D. in 1914. He studied throat and nose surgery in London in 1906, and in the following year went to Vienna as demonstrator at Prof. Chiaris's throat and nose clinic. Subsequently he practised in Dublin. During the war of 1914-18 he served in the R.A.M.C.(T.) with the rank of captain, and was mentioned in dispatches. He was lent to the French authorities in Salonika for the purpose of treating wounded Serbian soldiers, and was later appointed liaison officer between the British, French, and Serbian Medical Services. The King of Serbia awarded him a gold medal for distinguished services. He was also made Chevalier of the Legion of Honour, and received the French Croix de Guerre. For services in Macedonia he was honoured with the Greek Chevalier Order of the Redeemer. Dr. Murphy was president of the Dublin Chamber of Commerce in 1924, and was a delegate to represent the employers of the Irish Free State at the International Labour Conferences of 1928, 1930, and 1931

Dr. C. S. NIMMO, who died at Jedburgh on Feb. 20 at the early age of 47, had practised there since 1922. Educated at George Watson's College and Edinburgh University, Charles Stuart Nimmo qualified M.B., Ch.B. in 1921 After holding house appointments at the Royal Infirmary, Edinburgh, he went to Jedburgh, where he soon established a large practice extending well over the Border country. His education was interrupted by the last war, for he enlisted in the Royal Scots in 1914 and was commissioned in the Seaforth Highlanders in the same year. He had played as a Rugby half-back for Scotland, gaining his cap in the match against England in 1920. He had been a member of the B.M.A. all his professional life, and was a representative at the Representative Meeting held in London last September. Dr. Nimmo was well known in many homes in Roxburghshire, rich and poor alike, and it is said of him that he not only brought healing but was known to carry food to people in the outlying districts who had been stranded by a snowstorm.

The death took place at Middlesbrough on Feb. 22 of Dr. J. BROWNLEE. Born in Edinburgh in 1878, James Brownlee was educated at Daniel Stewarts College and Edinburgh University, where he graduated M.B., Ch.B. in 1901, proceeding to the M.D. in 1904. After serving as house-physician to Prof. Wyllie in Edinburgh Royal Infirmary and to Dr. Buist at Dundee, he went into partnership practice in Middlesbrough, which continued for 35 years. For many years he was honorary physician to the North Riding Infirmary, and on his retirement was elected consulting physician. He served in the last war with the rank of captain, R.A.M.C., mostly in Mesopotamia. Brownlee worked for his profession in many ways. A life-long member of the B.M.A. and one of its severest critics, he had been president of the North of England Branch and was on the Branch Council for a number of years. He had been secretary, chairman, and on four occasions representative, of the Cleveland Division. A keen insurance practitioner, he was a member of the Middlesbrough Panel Committee from its formation, and had been its chairman. He had also been chairman of the local Public Medical Service. Brownlee was an active man, and fond of outdoor exercise and games, particularly golf, tennis, and badminton. By hard work he had built up and maintained a large practice, and he will be greatly missed by his many patients, for whom he never spared himself and to whom he always gave of his best, and by many personal and professional friends. He is survived by his widow, daughter, and son.

Dr. C. J. PINCHING, who died on Feb. 23 after a long illness in his 68th year, was a native of Gravesend and the third generation of a family which has practised in that town for the last 92 years. Charles James Pinching received his medical education at Guy's Hospital and at Oxford, taking the M.R.C.S., L.R.C.P. in 1902 and his M.B., Ch.B. in 1905. He joined the staff of the Gravesend and North Kent Hospital in 1906 and was senior surgeon there for 21 years. Of his operative skill there was no question, and had he wished he would undoubtedly have acquired merit in spheres wider than that of his local hospital, but his interest was there and to it he gave a lifetime of single-minded devotion. He also had a large private practice, and his opinion as a consultant was much sought and valued in North Kent. In the last war he was in charge of the local military hospital, and for his services there was awarded the O.B.E. He remained at work almost to the last, and until he finally gave up never missed his usual morning round at the Gravesend Hospital. His colleagues, patients, and personal friends mourn the absence of a loyal and devoted comrade.

We regret to announce the death on Feb. 28, after a long illness, of Dr. ALFRED LANG BODLEY at the age of 52. He was educated at Dean Close School, Cheltenham, and Clare College, Cambridge, where he took his B.A., and completed his medical studies at University College Hospital, qualifying M.R.C.S., L.R.C.P. in 1915. During the last war he served with the R.A.M.C., and was awarded the M.C. for gallantry. After returning to civil life he was house-surgeon at the District General and Hallam Hospitals, West Bromwich, before starting in general practice in Helston. In 1925 he returned to West Bromwich and settled down in practice there. He was surgeon to the West Bromwich and District General Hospital, an appointment he held until he was taken ill last year. Dr. Bodley was of a shy and retiring nature and exceptionally modest. He was devoted to his work in both general and hospital practice and was a sound clinician and a skilful surgeon. The loss of his valuable services will be keenly felt in West Bromwich and surrounding district.

By the untimely death on Feb. 14 of JOHN HUGH SCHOFIELD the medical profession has lost a most promising member, for although he had been qualified only a few months he had already shown himself to be whole-heartedly in love with his work, and his patients' welfare was always his first consideration. Born at Leeds in 1919, he was educated at Manchester Grammar School and later at King Edward VII School, Sheffield, where he obtained the higher school certificate at an early age. He received his medical education at Sheffield University, taking a prominent part in the various student activities there and serving for some time on the Union Committee. He qualified M.B., Ch.B. in 1942, and shortly afterwards was appointed assistant casualty officer and then house-physician at the Royal Hospital, Sheffield, where he quickly showed himself to be a most reliable and conscientious resident, and was deservedly popular with both patients and staff. As he was temporarily unfit for medical service with the Forces, he was appointed resident medical officer at the Royal Hospital Annexe, Fulwood, an appointment which he held at the time of his death

We regret to announce the death on Feb. 18 at Castlederg, Co. Tyrone, of Dr. KENNETH ROY THORNTON in his thirtieth year. He was the second son of the Rev. and Mrs. R. H. Thornton of Glasgow and was educated at the University of Glasgow, where he graduated M.A. in 1934 and M.B., Ch.B. in 1938. After holding house posts at the Western Infirmary and the Ear, Nose, and Throat Hospital, Glasgow, he entered the R.A.M.C. as temp. lieut. in Dec., 1939, and was promoted capt. a year later, but had to resign his commission, on account of ill-health, in June, 1941. He leaves a widow. He was a member of the B.M.A.

By the death last August, at the age of 63, of Mr. WALTER WELCHMAN the Medical Association of South Africa (British Medical Association) lost one of its most active members in the Union. He joined the Association in 1910, was honorary treasurer of the Witwatersrand Branch from 1917 to 1922, acted as representative at the Annual Representative Meeting held at Cardiff in 1928, and was president of the Southern Transvaal Branch in 1930–1. Mr. Welchman was born in Cape Colony and, after graduating B.A. at the University of Capetown, entered Guy's Hospital for his professional education and graduated M.B., B.S. of the University of London in 1905, taking the M.R.C.S., L.R.C.P. in the same year and the F.R.C.S. three years later. Returning to South Africa he settled in Johannesburg, where he built up a large surgical practice, and became surgeon (later consulting surgeon) to the Johannesburg Hospital and lecturer in clinical surgery in the University of the Witwatersrand. He contributed a number of articles to the *South African Medical Journal* and to the *Transvaal Medical Journal*, mainly on the surgery of cancer. He leaves a widow and family.

News has been received of the death at sea of Mr. ISAK NAHUM BLUSGER, F.R.C.S., who came to this country from South Africa and studied medicine at St. Bartholomew's. After qualifying in 1934 Blusger held several house appointments, including those of senior house-surgeon at his own hospital, house-surgeon at the Royal National Orthopaedic Hospital, and resident surgical officer at the Connaught Hospital, Walthamstow. In 1938 he took his Fellowship, and before he sailed from this country at the end of last year to join the Army in South Africa he was resident surgeon under the E.M.S.

News has been received of the death in Boston on Dec. 29 of Dr. E. G. BRACKETT, editor of the *Journal of Bone and Joint Surgery*, who was universally respected and regarded with affection by all his friends. We are indebted to a colleague for the following appreciation:

"I first met Dr. Brackett in the early days of my practice in Boston. He was then a medical student, handicapped by hip disease. This was actually a fortunate misfortune, for he was treated by Dr. Bradford and afterwards became his associate in practice. Bradford, the outstanding representative of self-contained orthopaedic surgery, was of a character and quality to attract followers, and founded what became known as the Boston School. He was dependent on the Children's Hospital for clinical material for teaching, and to supplement the deficiency Goldthwait established a department for adult orthopaedics at the Massachusetts General Hospital. This service was afterwards taken over by Brackett and conducted with great efficiency until his retirement at the age limit. This developing stage of orthopaedic surgery involved acrimonious controversy, in which Brackett took no part. He soon achieved a reputation for fairness and integrity, which made him acceptable to all factions, and in 1905 he was elected president of the American Orthopaedic Association.

"Dr. Brackett had great executive ability, which he first demonstrated when he took charge of a hospital ship sent from Boston to Cuba during the Spanish War. In the last war he was appointed a personal assistant to the Surgeon-General, as Director of Orthopaedic Surgery with the rank of Colonel, a post which he administered with great efficiency. Perhaps Dr. Brackett's most valuable and distinctive service in the establishment of the present standing of orthopaedic surgery was his editorship of the *Journal of Bone and Joint Surgery*, the organ of the American and British Orthopaedic Associations and of the American Academy of Orthopaedic Surgery, which is without a rival in its representative and comprehensive quality. Dr. Brackett was fortunate in retaining his activities to the end, and died in harness in his eighty-third year."

The following well-known medical men have died abroad: Dr. WILLIAM DICK CUTTER of Chicago, an authority on medical education, aged 63; Dr. CHARLES DAVISON, formerly professor of surgery at the Chicago Medical College, aged 84; Dr EUGENE STERLING KILGORE, since 1930 professor of clinical medicine at the University of California Medical School, aged 63; Dr. RUDOLF ABEL, emeritus professor of hygiene at Jena University, author of a hand-book of practical hygiene and co-editor of the *Zentralblatt für Bakteriologie* and *Gesundheits-Ingenieur*, aged 74; Dr. CAREY CULBERTSON, for many years professor of obstetrics and gynaecology at Ruskin Medical College, Chicago, aged 71; Dr. GERARDO LAGUARDIA, dean of the Faculty of Medicine, Asunción, Paraguay; Dr MARCHAND, Commander of the Legion of Honour, professor of the Paris Faculty of Medicine and member of the Académie de Médecine; and Dr. ALFRED SIMPSON TAYLOR, professor of clinical surgery in the department of neurology of Cornell University Medical College, aged 73.

The Services

Capt. E. Maclaine, R.A.M.C., has been appointed O.B.E. (Military Division) and Warrant Officer Class I (Assistant Surgeon (British Cadre) (1st Class)) C. M. E. Eyles, Indian Medical Department, M.B.E. (Military Division).

Prob. Temp. Surg. Lieut. N. S. Daw, R.N.V.R., has been mentioned in dispatches for good services in tending survivors after H.M.S. *Penylan* was lost.

CASUALTIES IN THE MEDICAL SERVICES

War Subs. Capt. VIAS MICHAEL SKOUFARIDES, R.A.M.C., is included as "died" in an Army Council Casualty List published on March 6. He entered the R.A.M.C. as lieut. in Aug., 1940, and was promoted capt. a year later.

Prisoners of War.—Major W. H. Dowell, R.A.M.C., Capt. M. T. O'Sullivan, R.A.M.C., Capt. T. S. Protheroe, R.A.M.C.

Wounded.—Temp. Major D. B. Jagger, R.A.M.C., Capt. G. M. Jolly, R.A.M.C., Capt. J. H. Keesey, R.A.M.C., Capt. G. O'Donnell, R.A.M.C., Temp. Major P. Spence, R.A.M.C.

DEATHS IN THE SERVICES

Col. SAMUEL ARTHUR ARCHER, C.M.G., A.M.S. (ret.), died at Twickenham on Jan. 9. He was the son of Col. S. Archer, A.M.S., and was educated at the Merchant Taylors' School, Crosby, and at the Victoria University, Liverpool, where he gained a scholarship in pathology. He took the M.R.C.S., L.R.C.P. in 1894 and entered the Army Medical Service, as it then was, in 1896. He saw active service in the Egyptian Campaign in 1898, receiving the Queen's and the Khedive's medals. During the last war he served in Belgium, France, and Italy, and was mentioned in dispatches in 1915. In 1917 he was promoted to full col. and became A.D.M.S. of the 7th Division, which he accompanied to Italy. He was again mentioned in dispatches and awarded the C.M.G. in 1919 and the Croce di Guerra. After his retirement in 1921 he resided at Godalming, Surrey. He was a member of the B.M.A. for 26 years.

Lieut.-Col. ERNEST ALAN ROBERT NEWMAN, C.I.E., I.M.S. (ret.), died at North Luffenham, Rutland, on March 2, after a short illness, aged 76. He was educated at Haileybury, Caius College, Cambridge, and St. Bartholomew's Hospital. He took his B.A. in the Natural Sciences Tripos at Cambridge in 1887, the M.R.C.S., L.R.C.P. in 1890, the M.B., B.Chir. in 1891. While on leave in 1899 he proceeded to his M.D. He gained a high place in the entrance examination for the I.M.S. in 1893, and was on active service on the North-West Frontier Province in the Malakand, Bajaur, Tirah, and Mohmand operations in 1897–8, gaining the Frontier medal with two clasps. Soon after, he joined the Bengal Civil Medical Department, and worked his way up through civil surgeoncies in several stations to the important post of civil surgeon and superintendent of the Medical School at Dacca in Eastern Bengal. Here an early training in architecture enabled him to draw up valuable and economical plans for the reconstruction of the hospital and medical school buildings, work which gained him the C.I.E. He was a sound, all-round practitioner, especially interested in ophthalmic surgery, and was the author of papers on the treatment of cataract as well as of a *Manual on Aseptic Surgery* for use in medical schools in India. After his retirement under the age limit before he reached the administrative grade (the common fate of I.M.S. officers who take higher qualifications before entering the Service), he was appointed ophthalmic surgeon to the Stamford Infirmary and consulting ophthalmic surgeon, Rutland County Council. He married Lilian Duggan, daughter of Lieut.-Col. J. Young, who survives him. He had been a member of the B.M.A. for 28 years.

Lieut.-Col. JAMES HENRY HUGO, D.S.O., I.M.S. (ret.), died at Guildford on Feb. 28. He was born on July 16, 1870, and was educated at Foyle College, Londonderry, and at St. Bartholomew's Hospital, qualifying M.R.C.S., L.R.C.P. in 1895. He also took the M.B., B.S. of the University of London in 1896 and the D.P.H. of the English Royal Colleges in 1907. He held appointments at St. Bartholomew's Hospital, Nottingham General Hospital, and Dulwich Infirmary before entering the I.M.S. in 1896. He soon saw active service with the 31st Punjab Infantry on the North-West Frontier of India in 1897, and greatly distinguished himself in the siege of Malakand and with an expedition into Upper Swat in 1897–8, winning the D.S.O. and the Frontier medal with two clasps. It is generally understood that he was recommended for the Victoria Cross for a particularly gallant action at this time. He next entered the Political Department and held a number of appointments as residency surgeon in Indian States, culminating in the prize post of residency surgeon, Kashmir, in 1914. During the war of 1914–21, including the after-troubles in India, he returned to military employment in charge of a large hospital in the Punjab and was selected for the Légion d'Honneur, Croix de Chevalier, some of which had been sent out for distribution in India. In 1925 he retired under the age limit, but his service in the Political Department was rewarded by his selection for the important administrative post of Director of Medical Services, Jammu and Kashmir, in the same year. After his final retirement from India he resided at Guildford. He had been a member of the B.M.A. for 47 years. His elder brother, Lieut.-Col. E. V. Hugo, C.M.G., I.M.S. (ret.), survives him.

Universities and Colleges

ROYAL COLLEGE OF SURGEONS OF ENGLAND

A meeting of the Council of the College was held on March 11, with Sir Alfred Webb-Johnson, President, in the chair.

A Diploma of Fellowship was granted to Frederick Noel Glover.

Diplomas of Membership were granted to D. G. Crawshaw, R. Greenwood, Kathleen M. Lawrence, and Helen G. T. Maycock.

Diplomas in Ophthalmic Medicine and Surgery and in Medical Radiology were granted, jointly with the Royal College of Physicians of London, to the following successful candidates:

DIPLOMA IN OPHTHALMIC MEDICINE AND SURGERY.—Hilda Barker, H. Bentley, J W. Bishop, C A Brown, R. A. D. Crawford, R C Jack, D J Pierse, A Senn, A. Smith, W T Swanton, R. M Thornton

DIPLOMA IN MEDICAL RADIOLOGY.—G M Ardran, J S Mitchell, D C Porter, W Shanks, Phyllis Wade

Elections to Council

The election of five members of the Council of the Royal College of Surgeons of England will take place on July 1. By March 15, the last day on which nominations could be received, the names of the following 12 candidates had been forwarded to the secretary: Prof. Seymour Barling, Sir Lancelot Barrington-Ward, Major-General P. H. Mitchiner, Mr. A Tudor Edwards, Mr. L. R Broster, Mr John B. Hunter, Prof. J. Paterson Ross, Mr. A Dickson Wright, Prof. P. J. Moir, Air Commodore Stanford Cade, Mr. R. Watson-Jones, Mr. R. Milnes Walker, and Surg Capt. Lambert Rogers.

The five vacancies were caused by the retirement in rotation of Sir Cuthbert Wallace and Prof. Seymour Barling, the death of Emeritus Prof. L. R. Braithwaite, and the resignation of Mr. W. Sampson Handley and Sir Hugh Lett.

Present constitution of the Council: *President*, Sir Alfred Webb-Johnson; *Vice-Presidents*, Surg. Rear-Admiral G Gordon-Taylor and Mr. H. S. Souttar; *Members*, Sir Cuthbert Wallace, Mr W. Sampson Handley, Prof. A. H. Burgess, Mr. Victor Bonney, Prof. G. Grey Turner, Sir Hugh Lett, Sir Robert Kelly, Sir James Walton, Sir W. Girling Ball, Prof. Seymour Barling, Brigadier C. Max Page, Mr. W. H. Ogilvie, Surg. Rear-Admiral C. P. G. Wakeley, Mr. L. E. C. Norbury, Prof. R J. Willan, Mr. C. A. Joll, Mr. V. Zachary Cope, Prof. Harry Platt, Prof. E. F. Finch, Brigadier Hugh Cairns, and the late Emeritus Prof. L. R. Braithwaite.

Medical Notes in Parliament

Non-pulmonary Tuberculosis and Pasteurization

Mr. RICKARDS on March 3 asked the Parliamentary Secretary to the Ministry of Food, "in view of the increase in the death rate in London of 67%, alleged to be due to non-pulmonary tuberculosis, in 1941 as compared with 1938," to refuse to make pasteurization compulsory in London, as this death rate was higher than the average rate in the country, where the proportion of raw milk drunk was higher. Mr. MABANE said this question appeared to rest on the assumption that non-pulmonary tuberculosis was due wholly or mainly to tuberculous infection of the bovine type and that its incidence was therefore an index of the amount of bovine infection. There was no evidence for this assumption. It was estimated before the war that only 30% of the cases of non-pulmonary tuberculosis at all ages were due to bovine infection. It was to be expected that since the outbreak of war the incidence of non-pulmonary tuberculosis should have increased more in towns, where the risks of human infection were greater and were accentuated by war conditions, than in the country. The statements referred to by Mr. Rickards did not bear directly on the question of pasteurization.

Future of Osteopaths, Herbalists, etc.—Dr. PETERS asked whether, having regard to para. 427 of the Beveridge report, medical herbalists, osteopaths, naturopaths, homoeopaths, and others engaged in healing the sick would be officially recognized and their patients permitted to receive treatment from them under the future medical service scheme. Mr. BROWN replied on Feb 24 that arrangements necessary for ensuring a comprehensive health service in the sense envisaged by Assumption B of Sir William Beveridge's report were under consideration. He was not yet in a position to make any further statement on the matter.

Medical Examination of Directed Workers.—Mr. ERNEST BEVIN said on Feb. 16 that where workers alleged they were unfit for jobs in which the employment exchange proposed to place them, they were referred to an independent medical referee, unless they could produce satisfactory evidence from their own doctors. He had made arrangements that women called up to industry under the National Service Acts should be seen by a doctor if the exchange had any doubt about their fitness. He proposed to apply these arrangements to other workers receiving National Service Officer directions or being transferred away from home.

Financial Help for Tuberculous Persons.—Mr. BROWN said on Feb. 18 that detailed arrangements for the financial scheme for persons leaving work on account of tuberculosis, announced by him in the House in October, were in an advanced state. He hoped it would be possible to bring the allowances into operation early in the coming financial year. They would cover all persons who suffered loss of income by giving up work to undertake treatment for tuberculosis, including nurses

Silicosis Medical Board.—Mr. HERBERT MORRISON, replying on March 9 to Sir Wm. Jenkins, said the Medical Board for Silicosis and Asbestosis comprised eight full-time medical officers working in four panels under a chief medical officer. The board was appointed by the Home Secretary and was directly responsible to him. Appointments were for a definite term but were capable of renewal. The members were not established civil servants and had no pension rights. There had been no change in the personnel of the board since it was established in 1931.

Tuberculosis in Lancashire.—The monthly average of pulmonary tuberculosis cases awaiting admission to institutions in the administrative county of Lancashire was 57 in 1941 and 89 in 1942. The average waiting period for ordinary cases is estimated to have been about 14 days in 1941 and about 21 days in 1942. Steps are being taken to relieve the demand for beds for tuberculous cases in various parts of the country by recourse to suitable beds in E.M S. hospitals

Notes in Brief

The removal from farm premises to a market of cattle affected with tuberculosis in a clinical form is prohibited by the Tuberculosis Order. As regards other cattle Mr. R. S. Hudson says it would be impracticable to require the passing of a tuberculin test as a general condition of entry to markets.

The proportion of men called up for the Army but rejected on medical examination is 20%.

Medical News

The Industrial Health Advisory Committee just set up has Mr. Bevin as its chairman and Mr. G. Tomlinson, M.P., chairman of the Rehabilitation Committee, as its vice-chairman. The medical members are: Lord Moran (P.R.C.P), Prof. J. A. Ryle, Prof. A. W. Ellis, Sir Wilson Jameson, Dr. A. J. Amor (Deputy C M.O., Ministry of Supply), Dr. E. R. A. Merewether (Senior Medical Inspector of Factories), Dr. Charles Hill (Deputy Secretary, B.M.A.), Dr. M. W. Paterson (Secretary, Association of Certifying Factory Surgeons), Dr M W. Goldblatt (Chairman, Association of Industrial Medical Officers). The other members are: Sir Wilfrid Garratt (H.M Chief Inspector of Factories), Dr. J. Fox (Government Chemist), Sir T. W. Phillips (Secretary, Ministry of Labour and National Service), Mr. E. G. Fudge (Ministry of Fuel), Mr. William Scholes and General A. C. Baylay (representatives of employers), Miss A. Loughlin and Mr. J. L. Smyth (representatives of T U.C.), Mr. D. L. Smith (Department of Scientific and Industrial Research)

A general meeting of the Medical Society for the Study of Venereal Diseases will be held at 11, Chandos Street, W., on Saturday, March 27, at 2 p.m., when there will be a discussion on "Jaundice in Syphilitics," to be opened by Major J Marshall, R A.M.C., followed by Dr. J. McMichael (for J. H. Dible and J. McMichael) and Major T. E. Anderson, R.A.M.C.

A meeting of the Medico-Legal Society will be held at 26, Portland Place, W., on Thursday, March 25, at 5 p m., when a paper will be read by Dr. C. Keith Simpson on "Rex *v.* Dobkin (the Baptist Church Cellar Case)."

Following his preliminary meeting on March 9 with members of the medical profession, which is reported elsewhere in this issue (p. 359), the Minister of Health saw representatives of the County Councils Association, the Association of Municipal Corporations, and the London County Council on March 10, and of voluntary hospitals on March 11. The medical members at the latter meeting were: Nuffield Trust, Sir Farquhar Buzzard; King Edward's Hospital Fund for London, Lord Dawson and Sir Hugh Lett; British Hospitals Association, Lord Horder and Dr. G. C. Anderson.

Major Anthony Turner Andreasen, I.M.S., Prof. John Henry Gaddum, Sc.D., M.R.C.S., Dr. Robert Kirk, Mr. Duncan Metcalfe Morison, F.R.C.S Ed., and Mr. William James Stuart, F.R.C.S.Ed., were elected Fellows of the Royal Society of Edinburgh on March 1.

Sir Godfrey Huggins, F.R.C.S., Prime Minister of Southern Rhodesia, has taken over the portfolio of Minister of Defence in the Southern Rhodesian Cabinet.

The council of the Harveian Society of London has awarded the Buckston Browne Prize to Dr. E. Johl of Johannesburg, South Africa, for his essay on "The Evaluation of Methods of Physical Training and the Best Scheme for General Application."

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* during the week the only large fluctuations in the returns for infectious diseases were large rises in the incidence of measles and of whooping-cough—1,867 and 205 respectively.

In the trends of scarlet fever, diphtheria, and whooping-cough the only variations of note occurred in Lancashire. Here scarlet fever fell by 32 and diphtheria by 29, while a rise of 43 was reported for whooping-cough.

The notifications of measles during the week were over 2,000 more than the maximum weekly total during the last epidemic, in 1940–1. The largest increases during the week were those of Warwickshire 321, Yorks East Riding 164, Yorks North Riding 182, London 179, Middlesex 168, Durham 152, Gloucestershire 152, Essex 123, Wiltshire 128. In Yorks West Riding measles has been on the downgrade during the past month, notifications in the week under review falling by as much as 347.

In *Scotland* notifications of diphtheria, measles, pneumonia, and whooping-cough were up by 37, 85, 37, and 28 respectively. The trend for the whole country was considerably influenced by the experience of Glasgow, where the increases were: diphtheria 22, measles 70, and whooping-cough 36.

In *Eire* the incidence of diphtheria rose by 30%, from 96 to 126 cases; 55 of these cases were recorded in the city of Dublin, where an epidemic has been in progress since the beginning of the year. In January and February the deaths from diphtheria in this city were 23.

In *Northern Ireland* 72 cases of measles—a rise of 20—was reported from the outbreak in Belfast.

Quarterly Returns for Scotland

The quarterly return for the fourth quarter of 1942 for Scotland showed that the birth rate continued at a relatively high level, and that the death rate was below the average. The birth rate was 17.5 per 1,000, or 1.1 above the average of the December quarters of 1937–41. The infant mortality was 66 per 1,000 registered live births—12 below the five-years' average—and was the lowest rate recorded for the fourth quarter of any year. The number of stillbirths was equivalent to a rate of 38 per 1,000 total births. Maternal mortality was 3.6 per 1,000 live births, or 1.3 below the five-years' average. The general death rate was 12.2 per 1,000, or 0.8 below the five-years' average. The death rate from all forms of tuberculosis was 71 per 100,000, and that from respiratory tuberculosis was 55. These rates are 1 and 2 below those for the fourth quarter of 1941, but were 4 and 3 respectively above the average of the fourth quarters of 1937–41. The death rate from the principal epidemic diseases was only 17 per 100,000, the lowest rate ever recorded for a fourth quarter.

Included with the quarterly return is a preliminary statement for the whole year. Live births numbered 90,694, giving a rate of 18.1 per 1,000, or 0.5 above the average. Deaths from all causes numbered 64,962, equivalent to a rate of 13.0 per 1,000, or 0.7 below the average. The excess of births over deaths—25,732—was the largest since 1931. The number of deaths from the principal infectious diseases was exceptionally low: only 1,060 deaths were certified as due to one or other of these conditions. The lowest number previously recorded was 1,825 in 1938. The death rate from all forms of tuberculosis was 80 per 100,000, and 61 from respiratory forms. The rates for 1941 and 1940 were 83 and 80 for all forms, and 62 and 61 for tuberculosis of the respiratory system.

The Week Ending March 6

The returns for infectious diseases in England and Wales during the week included the following: scarlet fever 1,928, whooping-cough 1,876, diphtheria 827, measles 19,200, acute pneumonia 1,450, cerebrospinal fever 91, dysentery 68, paratyphoid 7, typhoid 2. Deaths from influenza registered in the great towns numbered 79.

No. 8

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended Feb. 27.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included) (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths; and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

ANY QUESTIONS?

Calcium in Pregnancy

Q.—*Is the use of calcium in pregnancy still recommended? Many obstetricians seem to think that it may prolong pregnancy and harden the foetal skull.*

A.—During the last two trimesters of pregnancy there is an increased need for calcium. This can and should be obtained from food. Milk and cheese are the best sources of calcium, green vegetables less so. It is essential that pregnant women take their full ration of these in some form or other. The ideal amount of milk would be a quart a day, since this would meet all requirements for calcium and phosphorus. There is some evidence from America that too much calcium and vitamin D may lead to early calcification in the foetal bones. I do not know of any evidence that pregnancy is prolonged through hardening of the foetal skull because of this.

Treatment of Chilblains

Q.—*What is the best treatment for chilblains?*

A.—Erythema pernio is the outward sign of the inability of the skin, including its small blood vessels, to adapt itself to low temperatures. The endocrine glands, through the vegetative nervous system, control the skin vessels, which play an important part in the regulation of the heat of the body. It cannot be said that there is any "best treatment" of chilblains. It is more important to treat the patient who has the chilblains. In some cases there may be endocrine imbalance, and administration of dry thyroid extract in doses of 1/2 to 1 gr. twice daily may do the trick. Where chilblains and amenorrhoea coexist in a girl, both conditions may respond to an oestrogenic hormone. A high protein diet will increase the metabolic rate and production of body heat, but wartime restrictions make it difficult to obtain such a diet. If the endocrine imbalance is secondary to emotional disturbance, then the latter may be assuaged by sedatives. It appears that in some cases septic or tuberculous foci are of aetiological significance. Many cases have cleared up after administration of vitamin D and calcium. Some cases, too, have responded to vitamin P. General measures, such as massage, exercise, physiotherapy, and ultra-violet light therapy, will improve metabolism and the peripheral circulation, but it is obvious that the practitioner would not be likely to advise these unless the chilblains were severely handicapping the patient and were unresponsive to the other measures. As to local treatment, the extremities should be kept warm, and if the lesions itch the following paint can be applied: phenol liq. ♏ x, tr. iod. mit. ♏ lx, and aq. camph. to 1 oz.; ung. iod. denigres. may be applied to the broken chilblains.

Allergy to Liver Extract

Q.—*A patient suffering from pernicious anaemia has been given injections of three of the most reliable preparations of liver extract with the same result—namely, severe allergic reaction with shock and urticaria. The only preparation which did not produce a reaction of the kind is now unobtainable. I am told that there are now no oral liver preparations made. Can anyone advise me how to continue to treat the case in the circumstances and whether it is possible to desensitize with fractional doses of a parenteral liver extract?*

A.—Desiccated stomach is in fairly free supply and is specifically intended for patients who are unable or unwilling to take liver by injection. Concentrated preparations of stomach are usually more acceptable than plain desiccated stomach. They are palatable, and the maintenance dose is of the order of 5 grammes a day. Successful desensitization has been reported in liver allergy. A standard intramuscular liver extract is used and an injection is given daily, the doses on successive days being 3 m., 5 m., 7 m., 10 m., 13 m., 17 m., 20 m., 25 m., 35 m. When the final dosage has been reached the interval between injections may be increased until the patient is receiving 2 c.cm. a fortnight. A preliminary skin test should be made with the liver extract, and if there is a very strong cutaneous reaction the extract should be diluted tenfold or more with saline and the course of treatment lengthened accordingly.

Swollen Legs: Cause Unknown

Q.—*A girl of 20 consulted me on account of extreme swelling of the legs from ankle to thigh. The swelling appeared to be a thickening of the subcutaneous tissues. There was no oedema and no discoverable vascular abnormality. The swelling had been present since the commencement of her menstruation and was said to be worse at her menses. It had also been made worse by excessive standing at her work during recent months. There was no swelling of her arms and no other abnormality was detected. Is there any help to be given in diagnosis and treatment?*

A.—This condition is not very uncommon and unfortunately does not respond very satisfactorily to treatment. It seems to be a local expression of dyspituitarism, and, as in the present instance, is often associated with the menstrual cycle. Combined treatment by pituitary and thyroid helps to relieve in some cases.

INCOME TAX

Income from Property in Dublin

D. explains that until recently his wife's income from property in Dublin was assessed on the "annual valuation" for purposes of British income tax; it has now been assessed on the basis of the "profit" derived from the property. Is this correct?

*** Yes. The tax is chargeable upon "the full amount of the profits or gains . . ." of the year preceding the year of assessment. Tax would be charged on the "annual valuation" if it was unlet but retained for the use of the owner—e.g., as an alternative residence.

LETTERS, NOTES, ETC.

Sedimentation Rate

Dr. L. A. WINDSOR-MCLEAN (St. George District Hospital, Kogarah, N.S.W.) writes: It has occurred to me after reading Dr. Della Vida's article on the sedimentation rate and the sedimentin index (Sept. 5, 1942, p. 278) that a perhaps easier, more accurate and geometrically correct method of measuring the sedimentation rate during the "period of constant fall" would be to lay down the straight-line curve which most nearly fits the experimental curve, and then, instead of measuring and calculating the factor $\frac{\text{“fall”}}{\text{run}}$ as suggested, rather with a protractor measure the angle which this straight-line curve makes with the abscissa. By looking up a book of mathematical tables the natural tangent of this angle will, as is obvious from elementary trigonometrical considerations, give straight out the figure $\frac{\text{“fall”}}{\text{run.}}$. The measurement of the tangent of the angle which it makes with the abscissa is the usual method adopted in co-ordinate geometry to measure the slope of a curve. The method has been adopted at this hospital and found convenient.

Perforated Gastric Ulcer at 19

Dr. DAVID KYLE (Brecon) writes: A soldier was recently admitted to the Breconshire War Memorial Hospital on his nineteenth birthday with a provisional diagnosis of "peritonitis" He had had vague abdominal pain for five days, culminating in an acute attack of vomiting accompanied by generalized abdominal pain two hours before his admission to hospital. Before that he had not reported sick. The previous history was uneventful; he was of the athletic type and had been Victor Ludorum at his school. Laparotomy revealed a perforated acute ulcer, with no surrounding induration, on the anterior aspect of the lesser curvature of the stomach, about three inches from the pylorus. It was easily accessible and easily repaired. The unusual feature is the youth of the patient, which made the diagnosis seem almost fantastic until the perforation was actually seen No statistics are available to me, but a perforated peptic ulcer at so early an age must be rare It would be interesting to know what the records show.

External Application of Opium

Dr J. MCLAREN (East Kilbride) writes: "The addition of opium to preparations applied externally is stated to be useless" (Martindale's *Extra Pharmacopoeia*, 21st ed, 1, 699). I must say that that is not my experience, and I would welcome views from colleagues on the subject. Both subjectively and objectively I have found a few drops of laudanum relieve a severe earache. Lot. plumbi c̄ opio I have also found effective in herpes zoster, urticaria, pruritus, and haemorrhoids.

A STANDARDIZED PLAN OF TREATMENT FOR GASTRO-ENTERITIS IN INFANTS

BY

C. ELAINE FIELD, M.D., M.R.C.P.

E.M.S. Base Hospital, Hemel Hempstead (Great Ormond Street)

D. MacCARTHY, M.D., M.R.C.P., D.C.H.

Surg. Lieut., R.N.V.R.; late Resident Assistant Physician to the Hospital for Sick Children, Great Ormond Street

AND

W. G. WYLLIE, M.D., F.R.C.P.

E.M.S., and Physician to Out-patients, the Hospital for Sick Children, Great Ormond Street

Following an outbreak of infantile diarrhoea and vomiting at a base hospital shortly after the onset of war, with the very high mortality rate of 80%, certain strict prophylactic measures were taken and a schedule of treatment formulated; these have resulted in a fall of the death rate to 23% and no recurrence of the disease in epidemic form. We therefore consider it worth while to record our routine procedure as a suitable standard of treatment for use in hospital and to report certain interesting signs of prognostic value and measures taken for prevention of this disease developing in hospital.

Treatment

Chart I shows the schedule of treatment practised in our infantile gastro-enteritis wards.

CHART I.—*Treatment of Gastro-enteritis*

The following is an outline of the treatment to be given in every case of diarrhoea and vomiting. Details must be adjusted to suit individual cases.

The Moment to Start.—As soon as there is any suspicion that the disorder is more than a dietetic upset. The following points may help in this distinction:

(a) *The Stools.*—Frequent, watery, offensive, or much mucus.
(b) *The Vomits.*—Exclude overfeeding, posseting, wind, etc.
(c) *A rise of temperature.*
(d) *Baby looks ill.*

1. *Give Castor Oil.*—Under 1 year, 1 drachm; over 1 year, 2 drachms.

2. *Stop all Milk*, and give 2- to 3-hourly by mouth half-strength Hartmann's Ringer-lactate solution. Add a little saccharin if necessary.

3. *The Daily Total Fluid Intake* should aim at 2½ oz. per lb. body weight, plus extra for dehydration not exceeding 10 oz. Slight dehydration may be restored by subcutaneous saline given early.

4. *If Dehydration Marked*, put on *Intravenous Drip* of half-strength Hartmann's solution containing 5% glucose for 24 hours, with only sips of water by mouth:

5 lb. ..	15 c.cm. (1/2 oz.)	per hour	= 360 c.cm.	in 24 hours
7 lb. ..	20 c.cm. (2/3 ,,)	,, ,,	= 480 c cm.	,, ,,
10 lb. ..	30 c.cm. (1 ,,)	,, ,,	= 720 c cm.	,, ,,
15 lb. or over	45 c.cm. (1½ ,,)	,, ,,	= 1,080 c.cm.	,, ,,

After 24 hours, feeds should be introduced according to the "pyloric schedule" (Note 6, second method). The drip must be slowed, provided dehydration is corrected, but must deliver enough to make up the day's total to the required amount. As the feeds increase so the drip is reduced. It should be the aim of treatment to make the baby independent of the drip by the end of the third day.

5. *Choice of Milk Feed.*—(1) Breast milk, if obtainable. (2) Half-cream dried milk, with or without lactic acid (e.g., half-cream lacidac, Cow & Gate). (3) Boiled milk with or without lactic acid (babies over 6 months dislike lactic acid milk). (4) Unsweetened condensed milk.

6. *Method of Introducing Milk Feed:*

First Method (when on Hartmann's solution by mouth).—After 24 hours continue the feeds, replacing part of the Hartmann's solution by the milk chosen as follows:

1 part	milk* to	8 parts Hartmann's	for 12 hours
2 parts	,, ,,	8 ,,	,, ,, ,,
4 ,,	,, ,,	6 ,,	,, ,, ,,
5 ,,	,, ,,	5 ,,	,, ,, ,,

and so on until correct strength for age is reached. Sugar should be gradually introduced when a half-strength milk mixture is reached. (N.B.—Mix the Hartmann's solution and milk immediately before the feed.)

Second Method.—A "pyloric" schedule of feeding, to be used when changing from intravenous drip to bottle feeds. Choose one of the milk feeds as in Note 5 and dilute as described in Note 6. Give:

1 drachm	hourly,	3 feeds	12 hours (total 3¾ oz.)
2 drachms	,,	3 ,,	
3 ,,	,,	3 ,,	
4 ,,	,,	3 ,,	
6 drachms	1½-hourly,	4 ,,	12 hours (total 6 oz.)
1 oz.	2 ,,	3 ,,	
1½ oz.	2-hourly,	6 ,,	24 hours (total 21 oz.)
2 ,,	2 ,,	6 ,,	
2½ ,,	3 ,,	6 ,,	
3 ,,	3 ,,	6 ,,	

It may be necessary to go more slowly than this and even to alternate milk feeds with Hartmann's solution. With large babies the quantities may be doubled. Babies should have absolute rest, *if possible*, from midnight to 6 a.m.

7. *A Stomach Wash-out* given early in the treatment and occasionally repeated, but not more than once a day, is often effective in checking the vomiting.

A Rectal Wash-out given early in the treatment is effective when stools are particularly offensive with much mucus.

8. *Drugs.*—For collapse: nikethamide (coramine) 0·5 c.cm. intramuscularly every 2 hours up to six injections.

9. *Fresh Air.*—An overheated room lacking ventilation increases a baby's disposition to vomiting and diarrhoea. Warmth by hot-water bottles may be necessary, but open-air ventilation can be used with advantage.

10. *Special Note.*—There is a tendency to overtreat these babies. They collapse very easily. All medical and nursing procedures should be reduced to a minimum.

The Selection of a Suitable Fluid.—Most authors agree to a period of starvation before a milk feed is introduced, but opinions differ as to the most suitable fluid to give during this period by mouth or parenterally. The first function of such a fluid must be to re-establish or improve the excretion of the kidney, as this is the chief mechanism controlling the salt and water metabolism of the infant. Secondly, the substances contained in the fluid should approximate as closely as possible to those of plasma, and be in sufficient quantity to replace that lost by stool and vomit, acting as a good buffer counteracting the tendency to acidosis or alkalosis in these infants. Hartmann (1928) and Hartmann and Elman (1929) composed a fluid with these properties known as Hartmann's Ringer-lactate solution.

Liquor Ringer-Lactatis (Hartmann's Solution)
(Supplement to *B.P.C.* 1934, Part III, Formulary 1941)

	Metric	Imperial
Lactic acid	2·4 ml. ..	23 m.
Solution of sodium hydroxide ..	A sufficient quantity to neutralize the lactic acid	
Sodium chloride	6·0 g. ..	52½ gr.
Potassium chloride	0·4 g. ..	3½ gr.
Calcium chloride	0·2 g. ..	1¾ gr.
Distilled water to	1,000·0 ml. ...	20 fl. oz.

At a recent discussion at the Royal Society of Medicine Young (1942) showed that an infant is unable to concentrate solids in the urine to the same extent as an adult. Therefore in dehydration these products accumulate in the body. Although Hartmann's solution is slightly hypotonic, to ensure a good excretory function of the kidney we recommend diluting the fluid by half and adding glucose up to 5% for intravenous or subcutaneous use, but for oral administration we prefer to omit the glucose in view of the danger of intestinal fermentation accentuating the diarrhoea.

---

* When dried or condensed milk is used this should be reconstituted to whole milk before adding the requisite "part" to the Hartmann's solution.

The blood chemistry following the use of various types of fluids has been extensively analysed, and great importance attached to the plasma chloride level, by many workers, with inconclusive results. Hoag and Marples (1931) recommend alternating normal saline and 10% glucose for intravenous use, but Cooper (1937) suggests the addition of calcium gluconate to saline to accelerate the movement of the fluid from circulation to tissue spaces. We, however, consider estimations of plasma chlorides under saline therapy of doubtful therapeutic value, as in several fatal cases the chloride percentage had regained a normal level.

Quantity of Fluid Required.—The total quantity of fluid given daily was kept constant at 2½ oz. per pound of body weight except in cases of dehydration, in which extra fluid up to 10 oz. a day was added according to the degree of dehydration. It is unwise to exceed this quantity owing to the danger of producing oedema.

The choice of milk for the feeds does not seem so important as the method of its introduction, which must be very gradual in all cases, however mild, especially in those with a tendency to vomit. In the latter the introduction may have to be even more gradual than we state in the schedule. Children over 6 months of age with persistent diarrhoea were treated with apple and tea diet (Sheldon and Hall, 1939) with some success. but the danger of this treatment is its tendency to produce vomiting, which in our experience is a more serious symptom.

Chart II is our daily record chart. It facilitates calculations of feeds and shows at a glance the weekly progress of the case. Records for a single day have been filled in.

CHART II.—*Weekly D. and V. Treatment Chat*

Name : J—— D—— *Age* 3 months *Weight* · 10 lb.

Date	29/8/42						
Fluids lost: Stools .. Vomits .. Urine ..	 7 2 small N.A D.						
Fluids given: Intravenous .. Subcutaneous By mouth ..	 15 oz. — 17½ oz						
Day's total ..	32½ oz.						
Approx. fluid required ..	27½ oz. +5 oz.						
Estimate of dehydration ..	Moderate						
General condition .	Poor; restless						
Focal sepsis ..	0						
Operation ..	0						
Type of feed ..	Lactic acid milk +Hartmann's 1 in 4, 2½ oz. 3-hourly—7 feeds						
Drugs .. .	0						
Character of stool ..	Green, watery						
Other notes ..	Troublesome cough						

Intravenous Therapy.—Intravenous fluid was introduced through a Bateman needle (Allen & Hanburys) after cutting down on a vein. The internal saphenous or veins in the cubital fossa or on the back of the hand were the ones most commonly chosen. If the vacoliter to be used was not calibrated, this was done before starting the operation, by marking in 10-c.cm. units a length of adhesive strapping which if carefully adjusted can be transferred from one bottle to the next when they are changed. The rate of the drip varied according to the size of the dripper and the quantity of fluid required. Approximately 8 to 16 drops a minute will deliver 50 c.cm. in an hour. An accurate hourly record of the quantity of fluid given was kept on a chart (Chart III). It is unnecessary to heat the fluid but important to keep the baby warm with hot-water bottles.

Blood Transfusion (10 to 15 c.cm. per pound of body weight) was useful in cases with severe anaemia or gross sepsis, or in the second or third week when the progress of the child was unsatisfactory. Aldridge (1941) prefers plasma to blood for transfusions owing to the increased viscosity of the blood in these infants, but we consider blood of more therapeutic value provided dehydration is corrected first.

CHART III.—*D. and V. Daily Fluid Chart*

Name · J—— D—— *Weight*. 10 lb. *Date* · 29/8/42

Time	Reading on Scale (c.cm.)	Amount in Hour (c.cm.)	Rate of Drip (Drops/Min.)	Total for To-day (Approx. in Oz.)	Remarks	Fluid by Mouth	Vomits	Stools	Urine

Totals				15		17½ oz	2	7	

Total fluid for the day, 32 oz.

Relapses were of two types. (1) The infant who responded at first to treatment and then started to vomit again and had an increased number of watery stools. In the first relapse of this kind the full schedule of treatment was started again, omitting the castor oil, but in subsequent relapses the milk mixture was persisted with as far as possible by mouth and the remainder of the fluid requirement was given parenterally. (2) The second type occurred in infants who reached the convalescent stage with normal stools and then relapsed. This was fairly common, but the child appeared to gain a certain immunity to the disease, as there were no fatalities in second or third attacks. The full schedule of treatment was given for each relapse of this nature, usually starting with castor oil.

Drugs.—Several varieties of the sulphonamide group of drugs were given by mouth or intravenously for parenteral infections with unsatisfactory results. The importance of a good fluid excretion by the kidney during the administration of these drugs is well recognized, but in infantile gastro-enteritis, in spite of an adequate intake, this excretion is reduced to subnormal by excess elimination from the bowels, less often by vomiting and from insensible perspiration of the lungs in a febrile child. Fifty-two babies were given a course of eucortone and six infants were tried on nicotinic acid, but no significant change was noted, so these drugs were discontinued.

Results

From Nov., 1940, to April, 1942, 100 infants under 2 years of age were treated for gastro-enteritis at the Hospital for Sick Children, Great Ormond Street, and its base hospital at Hemel Hempstead. Twenty-three of these died—a mortality of 23%. Realizing that the mortality depends to a large extent on the type and severity of the disease, we attempted to assess these by instituting a system of "marks" for certain symptoms and signs—the higher the number of marks scored the greater the severity of the disease and the more serious the prognosis. Chart IV shows our marking system.

It was soon found that this system had too many fallacies to be of statistical value. For example, personal variations cannot be excluded, and therefore certain estimates are only approximate; also, some features of the illness, such as diarrhoea and vomiting, may never fully develop. This particularly applies to the worst type of infantile gastro-enteritis showing practically no dehydration, vomiting, or diarrhoea, but merely the toxic facies—a type in which the child may be dead in 24 hours. However, certain interesting facts of prognostic value evolved from our system; these seem worth recording.

CHART IV.—*An Index of Severity*

Features of the Illness	Scoring 2 Marks	Scoring 1 Mark	Scoring 0	Marks Scored
1. Weight of infant before onset of D. and V.	—	14% or more underweight	Less than 14% underweight or overweight	
2. Age	Under 6 months	6 months to 1 year	Over 1 year	
3. Where disease developed	—	In hospital	At home	
4. Duration of symptoms before treatment started	—	Over 3 days	0 to 2 days	
5 Appearance of infant (collapsed, toxic, shocked, ashen)	Severe	Moderate	Mild	
6. Dehydration ..	"	"	"	
7. Parenteral infection	Present at onset of disease	Arising after onset	None	
8. Maximum number of stools in 7 consecutive days	More than 40	30 to 40	Less than 30	
9. Maximum number of vomits in 7 consecutive days. (More than 14 scores 4 marks.)	8 to 14	—	0 to 7	
10. Altered blood in vomit ("coffee-grounds")	Present	—	Absent	
			Total ..	

Weight.—Cooper (1937) recognized the importance of the weight of the infant at the onset of the disease. In his series of 300 cases the mortality rose from 36.5% to 65.0% in those 30% or more underweight. Maitland-Jones (1933), however, considers the figure of 14% or more underweight for age as representing an atrophic infant, and this figure we chose as our criterion. Thirty children fell into this category and 12 died—a mortality of 40%.

Age.—In agreement with other authors we found the disease most lethal in the first six months of life.

Age of Child	No. of Cases	No. of Deaths	% Mortality
Birth to 6 months ..	65	17	26·2
6 months to 2 years	35	6	17·1

Where Disease Developed.—Of great significance was the high death rate in infants developing the disease in hospital as compared with those contracting it at home.

Disease Developed	No. of Cases	No. of Deaths	% Mortality
In hospital	46	15	32·6
At home	54	8	14·8

Length of Illness before Treatment Started.—The importance of starting treatment early has already been stressed. Our figures show that if treatment was begun within two days of onset of symptoms the mortality fell from 25.9% to 20%.

Treatment Started	No. of Cases		No. of Deaths		% Mortality	
0–2 days	40		8		20	
3–5	30	54	8	14	26·7	25·9
Over 5 days	24		6		25·0	

Dehydration.—In agreement with Campbell and Cunningham (1941) we found that the mortality was closely associated with the degree of dehydration, rising as the latter increased in severity.

Degree of Dehydration	No. of Cases	No. of Deaths	% Mortality
None	22	0	0
Slight	27	1	3·7
Moderate ..	17	3	17·6
Severe	34	19	55·9

Parenteral Infection, if present at the onset of the gastro-enteritis, carried with it a higher mortality, whereas infection developing after the onset was not of such serious prognostic significance.

Infection at Onset	No. of Cases	No. of Deaths	% Mortality
None detected ..	61	12	19·7
Present ..	38	11	28·9

Vomiting was an important symptom. More than 14 vomits in one week carried with it a high rate of mortality. "Coffee-ground" vomit containing altered blood was seen in 12 cases, only 2 of which recovered.

Maximum No. of Vomits in 7 Consecutive Days.	No. of Cases	No. of Deaths	% Mortality
0 to 7	59	4	6·8
7 to 14	16	4	25·0
Over 14	24	15	62·5

Diarrhoea.—We took a less pessimistic view of the frequent watery stool, finding it easy to control provided there was no vomiting. However, our figures suggest that if frequent stools persist longer than a week the prognosis is not so good.

Maximum No. of Stools in 7 Consecutive Days	No. of Cases	No. of Deaths	% Mortality
0 to 30	37	6	19·4
30 to 40	37	9	32·1
Over 40	21	8	61·5

Discussion

The treatment of infantile diarrhoea and vomiting is too often unsatisfactory and haphazard. The mortality from this disease varies from 14 to 88%—seeming to depend to a large extent on the severity of the disease, which, as already shown, is difficult to assess scientifically. The toxicity rises in epidemics, when the mortality may reach 100%. Rice and his co-workers (1937) report 16 outbreaks in 11 lying-in institutions in America from 1934 to 1936: 505 cases were affected, with a fatality of 46%. The accompanying table shows results from the literature.

Table showing Cases and Mortality Rates in the Literature

Author	Institution	No. of Cases	% Mortality
Campbell and Cunningham (1941)	Park Hospital	574	27·7
Cooper (1937)	Royal Hospital for Sick Children, Glasgow	300	47·2
Recorded by Cohen *et al.* (1933) ..	Brooklyn, New York	175	35·0
Rice *et al.* (1937) ..	Eleven lying-in institutions in America	505	46·0
Smellie (1939)	Birmingham	500	48·0

The treatment varied so considerably from author to author that no correlation could be detected between any special method and the recovery rate. In view of this and the unsatisfactory mortality rate, particularly in those developing the disease in hospital, it is our opinion that prevention calls for far greater study, especially in hospitals and nurseries for infants.

Prevention

As a result of our first epidemic at the base hospital in 1940, when 12 out of 15 infants died, the following preventive measures were taken:

1. Better spacing of beds, interspersing baby-cots with those of older children. The number of children in a ward was reduced to half the number of adults the ward was designated to hold.

2. Masks and gowns were worn by all attending any baby under 2 years old.

3. An isolation ward for babies developing gastro-enteritis was obtained, and medical officers were encouraged to send the infants there on the slightest suspicion of the disease.

4. Ventilation was improved in order to keep a cool moving air in the wards, and nurses were encouraged to keep the infants warm with hot-water bottles rather than raise the temperature of the ward.

These measures were effective in reducing the incidence rate and preventing another epidemic; but they are far from ideal, and further recommendations are suggested.

5. Whenever possible, treat an infant in its own home unless the condition it suffers from demands admission to hospital. In hospitals the risk of infection is enormous unless the cubicle system, and nurses trained in prevention of infection, are available.

6. When admission is essential, babies under 2 years of age should be nursed in cubicles.

7. If a baby contracts gastro-enteritis it should be kept in its cubicle, and on discharge the latter should receive proper cleansing and preferably remain empty for a day or two.

8. After the war, nurseries for infants under 2 years of age should be discouraged. This would particularly apply to nurseries in maternity homes. To overcome this problem the ideal maternity home could be divided up into separate cubicles for mother and child. This seems a justifiable step to take when such figures as those quoted by Rice and his co-workers (1937) are considered.

9. If an outbreak develops in an institution, further admission for infants under 2 years old should temporarily cease, as many infants as possible be sent home, and the remainder be widely separated among older children or adults. Where one room alone has been used for the children this should be closed, thoroughly cleaned, and aired.

Summary

A plan of treatment for infantile diarrhoea and vomiting which has worked with encouraging results is put forward as a basis for use by those in charge of sick infants. One hundred infants were treated by this method, with a mortality of 23%. Certain interesting figures of prognostic value are recorded, including the high death rate of 32.6% in infants developing the disease in hospital compared with those developing it at home. In view of this and the recorded high mortality in institutional epidemics, measures for the prevention of the disease in hospital and nurseries are given.

Adequate treatment demands team-work and probably presents as highly skilled a form of nursing as any in diseases of children.

MILITARY MEDICINE IN THE MIDDLE EAST

AN EXPERIENCE OF 13,542 CASES

BY

ERNEST BULMER, M.D.Ed., F.R.C.P.Lond.

Temp. Lieut.-Col., R.A.M.C.; Officer in Charge of a Medical Division; Honorary Physician, Birmingham United Hospitals

This paper is based on the work of the medical division of a large hospital situated in a base area in the Egyptian desert, and covers a period of eighteen months (March, 1941, to Sept., 1942); the cases were unselected admissions from local camps and from convoys from the forward areas. It seemed to me that a brief survey of the medical problems out here might be of interest in England. This climate, while on the whole healthy, is unsuitable for those prone to certain diseases, which should be better known to those selecting troops for service here. We work with limited clerical and much-depleted medical staffs. The turnover of patients is very large, and elaborate statistical analyses are impracticable. From official and private records a good idea of the larger disease groups can be got, but the rare diseases have had to take their proper place against the utilitarian background of war and will only be touched upon here.

The relation between medical and surgical admissions has ebbed and flowed with the tide of battle, but there have been roughly three medical to two surgical admissions. The types of case dealt with will be considered in large groups, and conclusions will be given rather than the arguments supporting them. Some of the conclusions will be at variance with accepted tropical teaching, but the controversial opinions expressed upon dysentery will be discussed in a fuller paper when time permits.

The approximate incidence of the cases, expressed in percentages, is given in Table I.

TABLE I.—*Percentage Distribution of Disease; 13,542 Cases*

Tropical diseases	45%
Acute and chronic respiratory diseases	17%
Skin diseases (including scabies)	15%
Functional and organic nervous diseases	7%
Infectious diseases	5%
Chronic digestive disorders	4%
Chronic rheumatism—articular and non-articular	3%
Diseases of kidneys and bladder	1%
Circulatory diseases	0.7%

Tropical Diseases

The figures relating to the various tropical diseases are given in Table II.

TABLE II.—*6,144 Cases of Tropical Disease*

Dysentery group	4,178 (2 deaths)
Short-term fevers	1,153
Malaria	735 (1 death)
Avitaminoses	34
Relapsing fever	19
Bilharziasis	18
Kala-azar	5
Leprosy	1
Effects of heat	1 (1 death)

The Dysentery Group

Diarrhoea is the most important disease of the Middle East, and nearly one-third of medical admissions were due to it. Although it is probable that, apart from a few cases of food poisoning, the cause is the dysentery bacillus, cases are divided into two groups according to whether blood and mucus are visible in the stools or not. If they are, the condition is called "dysentery"; if absent, "acute catarrhal enteritis" or "Gippy tummy." The distinction is useful, as it makes a rapid assessment of severity easy, and is to be objected to only when different causes are postulated. The duration of stay in hospital of 600 cases of dysentery was 19.5 days, and of 600 cases of acute enteritis 11.5 days.

Laboratories are overburdened by the routine attempt to isolate the dysentery bacillus; success varies, and depends upon collaboration between the laboratory and the ward, which is seldom perfect. A strong plea could be made for limiting laboratory examinations to a search for *Entamoeba histolytica*; dysentery can be adequately managed with minimal laboratory help, as severe cases must be treated on clinical indications just as urgently as must diphtheria.

TABLE III.—*Dysentery Group; 4,178 Cases*

Amoebic dysentery, including hepatic amoebiasis	36, or 1%
Acute catarrhal enteritis	2,313, or 55%
Bacillary dysentery	1,829, or 44% (2 deaths)

(Of positive isolations, Flexner 70%, Shiga 19%, Sonne 6%, Schmitz 5%)

Treatment.—The contribution which this war will make to dysentery will be an appraisal of the value of specific chemotherapy and probably the abandonment of the use of castor oil and salts. On my responsibility—it was then almost a crime—saline treatment was stopped in this hospital in the summer of 1941; I do not think the treatment is of value, and on theoretical grounds it has much to condemn and little to commend it. Our usual treatment is rest in bed, ample fluids, a bland diet, and morphine to relieve colic in a few cases; dysentery has not, on the whole, been severe, so that in only about 10% of cases is any further treatment necessary. In patients whose diarrhoea persists more than seven days and who show active inflammation on sigmoidoscopy, and in all severe cases, one of the sulphonamide group has been given. Sulphaguanidine has been available since April, 1941, and both sulphanilamide and sulphapyridine have been used more recently. The conclusions we have reached are that sulphanilamide in tablets is of limited value; sulphapyridine and sulphaguanidine seem to be of equal value, and as specific in dysentery as the former is in pneumonia. As sulphaguanidine does not upset the patient it is the drug of choice in both acute and chronic dysentery; in the few cases of non-specific ulcerative colitis treated there has been no improvement. While the use of Shiga serum in very severe cases is compulsory, I have treated a few with double doses of sulphaguanidine, and recovery has taken place in attacks which were likely to have proved fatal.

Results.—There have been two deaths—one from exhaustion when adequate supplies of sulphaguanidine were not available, and the other that of a patient who already had a pericolic abscess when he reached us from the Western Desert. One patient was invalided home after a very severe dysentery, as he developed ulcerative colitis; a second patient was invalided home to South Africa owing to impairment in his health—he had been a prisoner of war; three patients were temporarily re-graded for base duties for three months. The remaining patients made a complete recovery. I regard this as a creditable record in such a disease, and I think it must be attributed to the use of sulphaguanidine in all the severe and prolonged cases: chronicity with permanent ulceration was not allowed to occur. Every case with diarrhoea lasting for more than 10 days was sigmoidoscoped.

Short-term Fevers

Approximately 2,000 patients (15% of the series) were admitted with "P.U.O."—pyrexia often heralded by a rigor, headache, and perhaps vomiting, but without signs or symptoms pointing to inflammation of throat, lungs, bowels, or other organs. Naturally a routine procedure has been adopted for these cases: repeated physical examination, especially for splenic enlargement; twice-daily blood films for three days; an accurate temperature record. With such numbers blood counts are impossible except where there are special indications. From this group of 2,000 cases either the progress or the laboratory findings excluded malaria, meningitis, the enteric group, relapsing fever, and a certain number of cases of dysentery with a febrile onset without diarrhoea at first. An alarmingly large residue of 1,153 cases is left. Of these, 805 have been called "sandfly fever," a diagnosis which in most of them is probably correct, but as we have not had an epidemic it is not easy to be certain of sporadic cases. I feel that textbooks have claimed too much for the clinical picture of sandfly fever, for I have seen typical cases prove to be malaria, relapsing fever, and once poliomyelitis; in the absence of an epidemic it is wise to make the diagnosis with reservations. The other 348 cases of short-term fever remain an unexplained problem and offer a fruitful field for research; they have not borne any resemblance to true influenza.

The short-term fevers are the cause of much morbidity but no mortality, and require the services of a good laboratory; they must not be treated as malaria, as to do so trebles their stay in hospital and would be a serious waste of man-power. They are sources of anxiety only when they last more than four or five days, as more serious diseases have then to be considered.

Malaria

TABLE IV.—*Malaria; 735 Cases*

Benign tertian	597, or 81%
Malignant tertian	44, or 6%
Quartan	9, or 1%
Ovale	1
Clinical	84, or 11% (1 death)

Malaria has been mild, and very few cases of the pernicious type have been seen. It has not been a difficult disease once it was realized that almost any febrile condition could be malarial, and its response to treatment has been so dramatic that in a few days no further anxiety was felt. I am aware that in other theatres of war the problem is different. The treatment has been to give quinine in solution in doses of 10 gr. thrice daily until the patient is afebrile, then mepacrine hydrochloride (atebrin) 0.1 g. thrice daily for five days, and after two days' rest a sterilizing and anti-relapse course of pamaquin (plasmoquine), 0.01 g. thrice daily for three days. With a constantly changing population it is not possible to give rates of relapse after this standard course, but they would seem to be low. I was impressed with the number of relapses occurring among those who had not received the pamaquin course.

There has been one death; it resulted from acute haemolytic anaemia with haemoglobinuria during the pamaquin course—haemolysis was checked, but the patient died from pneumonia. Too much stress need not be laid on this case of blackwater fever, as we had a similar case during the treatment of pneumonia with sulphapyridine, and a second case without a discoverable cause: both recovered.

The guiding principle in malaria has been to withhold quinine until the diagnosis has been established by the laboratory, unless (1) the patient is very ill and delay may prove fatal, or (2) the clinical picture together with an enlarged spleen makes malaria probable although repeated blood films have been negative. Eleven per cent. of the cases fell into this group of "clinical" malaria.

Avitaminoses

It is a tribute to the supply services that so few cases of deficiency disease have occurred: of the 34 cases admitted 31 were due to severe pellagra in non-British troops—there were no deaths. Nicotinic acid was given to the worst ones, and prompt modification of the diets in their camp put a stop to the outbreak.

Three cases of beriberi were admitted from the Western Desert; one was of the fulminating type with oedema and peripheral neuritis: this man died before we could treat him. The other two cases were mixed beriberi—one severe with great cardiac enlargement on x-ray examination, and the other mild; one of these patients had been for many months on desert patrols, and the other had been in the besieged Tobruk garrison. Response to injections of B_1 was rapid.

Relapsing Fever

It was not until we had been out here for some months that it became recognized that a tick-borne type of relapsing fever occurred in the Western Desert and was transmitted to troops living in caves and in holes in the ground. The disease is presumably similar to that found in Palestine and Iraq, but differs from louse-borne and African tick-borne relapsing fever. We have diagnosed 19 cases, but undoubtedly some were missed. The spirochaetes are very scanty in the blood, and large numbers of films, in several bouts, may have to be examined before they are found. The paroxysms of fever are brief, seldom lasting more than 24 hours, and resemble those of malaria; one patient at different times had both diseases, and was unable to distinguish between them. The resemblance to sandfly fever is close, as headache is severe in both diseases: many mistakes have probably been made, as patients with sandfly fever are usually discharged before the twelfth day, the usual date of the next paroxysm of relapsing fever.

This type of relapsing fever is characterized by brief bouts of fever with severe headache, giddiness, and usually splenic enlargement; the interval between attacks is 10 to 14 days. In a fair proportion of cases after a few paroxysms there are signs of involvement of the nervous system—lymphocytic meningitis or cranial nerve palsies, or a combination of both. The course of the disease seems to be unaffected by intravenous arsenical preparations, and there is a proved case in which 17 relapses occurred in spite of treatment. Stovarsol by mouth is at present being tried, and appears to be efficacious. The practical points about this type of fever are its frequent confusion with malaria and with sandfly fever and the difficulties of laboratory diagnosis in the absence of a supply of experimental animals; if prolonged observation is practicable the syndrome is characteristic enough to warrant a clinical diagnosis, especially if the nervous system becomes involved.

Bilharziasis

Although 18 cases of bilharziasis have been admitted, the only British soldier infected had caught it in South Africa: troops are aware of the dangers of fresh water in Egypt. The remaining 17 patients were Mauritians who had been infected in their own country. All the cases were due to *S. haematobium*. The only symptom was haematuria, and treatment with injections of tartar emetic was effective.

Kala-azar

In certain areas of Africa there is endemic kala-azar which is resistant to antimony and which gives rise to a curious clinical picture; one such area in the Sudan provided many cases, and five were admitted to us. The first case was quite baffling: the patient had a continued fever, splenomegaly, and leucopenia, and was regarded as a case of enteric-group fever until the persistence of the temperature began to raise very grave doubts—all laboratory tests had been negative. Brigadier Sidney Smith, the Consultant in Tropical Medicine, saw the patient and recognized his case as similar to the ones he had seen from the Sudan. Three other cases were later admitted from the same district, all presenting the same picture; it is unlikely that there will be more, as the area is no longer of military importance. In addition to the above-mentioned features the daily temperature charts showed a double rise in 24 hours, which is typical of kala-azar. The leucopenia and neutropenia were noted in all cases; but, apart from a positive formol-gel test in two cases, laboratory investigations were negative. We were unable to find Leishman-Donovan bodies in the spleen, marrow, or lymph glands, nor could we culture them from the blood. A fifth case similar to the other four occurred in a negro from the Cameroons, another recognized endemic focus.

We did not have an opportunity of treating our cases, as they were all transferred to one hospital in Cairo, where they were treated with neostibene, a new synthetic drug; the results were, I understand, excellent.

Effects of Heat

In this inland desert district the summer temperature is very high, usually over 105° and occasionally rising to almost 120° in the shade, but the humidity is low. No case of heat stroke (hyperpyrexia) has been admitted, nor has the condition developed in any patient under medical treatment in the wards. On the surgical side there have been a few cases of post-operative hyperpyrexia, probably due to heat stroke. Numerous cases have been sent into hospital as heat stroke, but every one proved to be an infection—malaria, sandfly fever, or septicaemia. I have constantly urged that, while the usual measures for reducing temperature should be at once adopted, a search for the infection must be made, and an intravenous injection of quinine be given if there is even the flimsiest suggestion of malaria. In other districts in the Middle East heat stroke has, I understand, occurred.

One case of heat exhaustion has been admitted to hospital. This occurred in a man who had had heat exhaustion in the Red Sea, from which he had only partially recovered on disembarkation; his arrival in this area unhappily corresponded with the record heat wave in May, 1941, when the shade temperature was just under 120°. His symptoms were marked weakness and complete anorexia; he was wasted and dehydrated, the systolic blood pressure was 62 mm. Hg, the temperature was subnormal, and the blood showed marked haemoconcentration. He was vigorously treated with saline solutions by all routes, adrenaline, and cortin; but he failed to respond, and died of suppression of urine on the fifth day of his stay. The necropsy showed no macroscopic changes in any organ, and the pituitary and suprarenal glands were normal.

Respiratory Diseases

TABLE V.—*2,402 Cases of Respiratory Disease*

Acute:	
Tonsillitis and pharyngitis	1,171
Laryngitis, tracheitis, bronchitis	620
Primary pneumonia	169 (4 deaths)
Coryza	65
Chronic:	
Bronchitis, asthma, emphysema, bronchiectasis	337
Pulmonary tuberculosis	40 (2 deaths)

Respiratory diseases were responsible for 17% of the medical admissions. There is nothing remarkable about the acute group except the high incidence of tonsillitis. Every case of pneumonia was treated with sulphapyridine, and the mortality was very low. While there were many atypical cases, I did not think the disease was different from what it is in England. The number of chronic chest cases was not very high, but the group is most important, as 126 had to be either invalided to the United Kingdom or re-graded for limited service in the Middle East. Too much stress cannot be laid on the fact that chronic chest conditions are greatly aggravated by the climate in Egypt and Libya, and men prone to such troubles should not be sent out here.

Skin Diseases

Of the 2,142 cases admitted to the skin wards 639 had scabies, which seems to be less common than in England; the routine treatment was with Marcussen's ointment. Most of the skin diseases were the common ones seen in England; prickly heat has been uncommon.

Desert sores have been a big problem in the Middle East, and many cases have been admitted to the skin wards. While I am not competent to disentangle this dermatological puzzle, the clinical aspects are simple: the sores are indolent ones, usually multiple, on exposed parts, chiefly forearms and legs, and often due to infected abrasions or insect-bites. The factor common to all types is their slowness to heal outside of hospital, their rapid healing in hospital, and their satisfactory response to a variety of remedies *in hospital*. Any sore or wound may be infected with the diphtheria bacillus by droplet infection, and, rarely, this happens in desert sores. The single very indolent sore has been suspect, so we swab them as a routine measure. We have had at least two cases of extensive peripheral neuritis and one case of fatal heart failure in these diphtheritic desert sores.

Infectious Diseases

TABLE VI.—*703 Cases of Infectious Diseases*

Acute infective hepatitis	341 (1 death)
Diphtheria (faucial)	130 (4 deaths)
Mumps	118
Acute rheumatism	30
Enteric group	24 (6 deaths)
Measles (all forms)	17
Meningitis, benign lymphocytic	16
Poliomyelitis and encephalitis	8 (1 death)
Erysipelas	8
Meningitis, cerebrospinal	6
Scarlet fever	4
Meningitis, streptococcal	1 (1 death)

This table needs little explanation; the high incidence of acute infective hepatitis (epidemic jaundice), the very few cases of enteric fever, and the negligible occurrence of cerebrospinal fever and scarlet fever are obvious. It is probable that some of the patients with benign lymphocytic meningitis were unrecognized cases of relapsing fever. Mumps was almost limited to Seychellois and East African troops.

Acute Infective Hepatitis.—Although this has been the commonest infectious disease its aetiology is obscure and will remain so until a susceptible experimental animal is found. The disease is similar to the English variety, and no new treatment has been found; few cases are admitted in the pre-icteric febrile phase, when it is impossible to distinguish it from a short-term fever. The fatal case was admitted after a few days of jaundice; the patient did not seem particularly ill; but suddenly he became cholaemic and died within the first 24 hours.

Diphtheria.—Among so many cases of diphtheria in adults it is not surprising that the throat signs have often been atypical and resembled acute coccal infections or even quinzy—suspicious throats are oftener swabbed than at home. It is not possible to give figures showing the incidence of paralyses, but they have been of a severity that was quite outside my previous experience: recovery has been slow, but in all cases it was complete, and even two cases of diaphragmatic paralysis recovered. The mortality of 3% from diphtheria is not high.

Enteric Group.—The 24 cases include typhoid, paratyphoid, and clinical typhoid fever, without laboratory confirmation. The low incidence is the result of the satisfactory state of the troops with respect to inoculation, but I have been impressed with the severity of the cases due to *B. typhosus*: inoculation did not seem to have modified the course of the disease once it was contracted. The mortality rate of 25% would be much higher if only cases of typhoid fever were considered. The disease remains uninfluenced by any treatment but good nursing, and the sulphonamide group is ineffectual.

Other Causes of Illness

There is a small unanalysed group of cases—surgical conditions overflowing to the medical division, miscellaneous diseases, and rarities—which will not be dealt with. Table VII contains an analysis of conditions which would bulk large in an English hospital but which accounted for only 16% of the admissions here; the figures are available for only the last 7,190 admissions, but there has been no significant change in their admission rate over the whole period.

TABLE VII.—*Other Causes of Illness among 7,190 Admissions*

Nervous diseases		487
Organic	16	
Psychosis	15	
Psychoneurosis	456	
Chronic digestive diseases		291
Peptic ulcer	56	
X-ray-negative dyspepsia	213	
Other diseases	22	
Circulatory diseases		54
Effort syndrome	30	
V D H and other diseases	24	
Chronic articular and non-articular rheumatism		240
Urinary diseases		73
Acute nephritis	13	
Renal colic, oxaluria, etc	60	

Causes of Death

Thirty-two deaths have occurred, but seven were in untreatable diseases: cerebral tumour (2), cancer of stomach (1), cancer of hepatic ducts (1), acute monocytic leukaemia (1), acute myeloid leukaemia (1), tuberculous meningitis (1). Table VIII shows the causes of death in the other cases, and, where applicable, the percentage mortality of the disease.

TABLE VIII.—*Causes of 25 Deaths*

Diphtheria (faucial)	4 (3%)
Diphtheria (cutaneous)	1
Acute primary pneumonia	4 (2.4%)
Malaria—blackwater fever	1 (0.13%)
Pulmonary tuberculosis	2
Bacillary dysentery	2 (0.10%)
Enteric group	6 (25%)
Acute infective hepatitis	1 (0.3%)
Streptococcal meningitis	1
Heat exhaustion	1
Encephalitis	1
Staphylococcal septicaemia	1

Conclusion

I have tried to condense eighteen months' work into a few thousand words, and have had, perforce, to appeal to figures and tables—always dull things; it is hoped that the main problems of Middle East medicine have been made clear.

We have not been working under conditions to which we were accustomed in peacetime. This hospital is built on desert which was uninhabitable three years ago; every possible amenity has been provided and we have ample safe water, a good hot-water system to the wards, electric lighting from a mains supply, and every reasonable drug and instrument. Three-quarters of the patients have been treated in tents and only the minority in the few hutted wards, conditions which would be impossible in England but are by no means ill adapted to this climate. I feel that the results of treatment could hardly have been bettered under our peacetime civilian conditions.

To practise in a country where tropical disease is rife is to get a glimpse into the future which is opening out before the advances of chemotherapy. While much of tropical specific therapy is old, much is new, and it has been a unique experience to treat bacillary dysentery with the newer sulphonamides. If from the cases treated here the ones amenable to specific chemotherapy are excluded—malaria, amoebiasis, bilharziasis, kala-azar, the avitaminoses, pneumonia, cerebrospinal meningitis, tonsillitis, and bacillary dysentery—there are only small groups of cases still remaining refractory. There is no specific treatment for enteric fever, or such virus diseases as acute infective hepatitis, coryza, and encephalitis or poliomyelitis. Sandfly fever is not important from the point of view of treatment, as it is so brief. Finally, I would again draw attention to the adverse effect of this climate on chronic chest diseases.

SPECIFIC IDENTIFICATION OF THE CHIEF PATHOGENIC CLOSTRIDIA OF GAS GANGRENE

BY

G. F. PETRIE, M.D.

AND

DOROTHY STEABBEN, B.Sc.

The Lister Institute, Elstree, Herts

The isolation in a pure state and the identification of the chief anaerobes of gas gangrene—namely, *Cl. welchii*, *Cl. septicum*, and *Cl. oedematiens*—are everywhere recognized as being beset with peculiar difficulties, owing partly to the need of these bacteria for oxygen-free conditions of cultivation, and partly to their tendency to grow in cryptic association with other anaerobes in spite of prolonged efforts to obtain pure cultures. The method described below is likely to aid in their identification, since it depends upon the highly specific, lethal, and antigenic toxin which is characteristic of each of them. This method consists in growing the bacterial inoculum on the surface of agar to which an appropriate amount of one of the specific antitoxins has been added. During the growth of the colony toxin is produced, diffuses outwards from the colony, and interacts with the homologous antitoxin to form a delicate but unmistakable precipitate resembling a halo round the colony.*

The method is identical with that which was found by one of us (Petrie, 1932) to serve as a differential test for rough and smooth strains of meningococcus, pneumococcus, and *B. dysenteriae* (Shiga) and to establish a clear distinction between group 1 strains (type 1 and type 3) and group 2 strains of meningococcus (cf. Branham, 1940). When, for example, a smooth strain of group 1 meningococcus is grown on an agar plate containing 5% of the homologous immune serum a precipitate is formed round the colonies which is composed of the polysaccharide complex (the somatic antigen) in union with the protein of the specific antibody, whereas in the anaerobic group under discussion the precipitate consists, in the final analysis, of a purely protein aggregate—namely, the toxin molecule in combination with a variable number of the specific molecules of the homologous antitoxin. Molecular aggregates of each kind, irrespective of the chemical nature of the reacting substances, become linked together to appear as a macroscopic precipitate in agar, as described below; in a fluid medium the product of the reaction takes the form of floccules. Soon after the publication of the earlier paper the author made a limited number of observations on the effect of seeding the Park-Williams No. 8 strain of *C. diphtheriae* on agar plates containing diphtheria antitoxin, when ring-like precipitates were noted round the colonies.

Technical Details of the Method

The method is essentially a simple one, and any difficulties that may be encountered are likely to be due to the strict necessity for providing a high degree of anaerobiosis in order to obtain adequate surface growths on agar plates; this proviso applies particularly to *Cl. oedematiens.*

The medium used is 2.5% agar containing the ingredients that are added for the routine production in this Institute of high-grade toxins of the three anaerobes. The basal medium is a horse-meat infusion broth (1 lb. to 1 litre of tap-water heated to 95° C. with 0.5% acetic acid, neutralized and filtered) together with 3.5% Evans peptone and 0.5% sodium chloride; *p*H adjusted to 7.8, 2.5% agar added, and the medium tubed in 17-c.cm. amounts and steamed or autoclaved. Before pouring the melted agar the following ingredients are added to it in sterile solution when the temperature has fallen to about 45° C.

For *Cl. welchii*: 2 c.cm. of a mixture containing 5 g. glucose in 100 c.cm. of a sulphated horse-muscle extract (Macfarlane and Knight, 1941), bringing the final concentration of the extract in the medium to 10% and of the glucose to 0.5%. For *Cl. oedematiens*: 2 c.cm. of the sulphated horse-muscle extract, but *without glucose.*† For *Cl. septicum*: 2 c.cm. of a mixture containing 5 g. glucose in 100 c.cm. heated normal horse serum (56° C. one hour) so that the final concentration of serum in the medium is 10% and of the glucose 0.5%.

Lastly, there is added at the same time 1 c.cm. of a dilution in broth of the appropriate antitoxin, which, when added to 17 c.cm. of agar and 2 c.cm. of extract or serum mixture, represents approximately 8 I.U. per c.cm. of the final medium. The special ingredients can be mixed to provide a sterile solution, and it is doubtless an advantage to add to each mixture an amount of *l*-ascorbic acid, which favours anaerobic growth by virtue of its being a reducing substance, to give a concentration of 0.025% in the final medium.‡

After the plates are poured they should be dried in an incubator at 37° C. for at least 5 hours in order to prevent motile organisms from filming over the surface. The plates may be spread in the usual way, or a heavy inoculation with a platinum loopful of a pure or reasonably pure culture may be implanted on the agar at any chosen site. The plates are examined after 24 or 48 hours' incubation at 37° C. anaerobically. If the resulting colonies are well grown but show no precipitate the plates should be placed at room temperature aerobically and observed daily, because the haloes, especially those of *Cl. oedematiens*, may be slow in appearing.

---

* The Nagler reaction resulting from the diffusion of toxin from colonies of *Cl. welchii* on human serum agar plates is used to identify this bacterium (Hayward, 1941).

† There is reason to believe that for both *Cl. welchii* and *Cl. oedematiens* equally good results can be obtained by omitting the sulphated horse-muscle extract from the medium; the agar to be tubed should then be increased from 17 c.cm. to 19 c.cm.

‡ The special ingredients and antitoxin solutions should be kept preferably in a refrigerator, or otherwise in the coolest place available, and great care should be taken to preserve their sterility. Assistance will gladly be given in the technical application of the method if inquiries are addressed to the Lister Institute, Elstree, Herts.

Characteristic Features of the Precipitates

There is usually no difficulty in recognizing the halo against a black background with ordinary good daylight, but a simple magnifying-glass or even a binocular dissecting microscope of low magnification is helpful on occasion. At an early stage, when the zone of precipitate is narrow and of slight density, or when it is desired to light up the structural details of the halo to the best advantage, a simple improvised illuminator can be used. This consists of a black plyboard, 1 × 1½ ft., with a back-rest and a central opening about one inch in diameter, which may be fitted with an iris diaphragm; an electric light provided with a white reflecting shade is placed behind the opening in a position which allows only the reflected light to illuminate the desired portion of the plate. The best view is obtained by ensuring that the external surface of the agar plate is clean and by removing the cover.

When the precipitate has been laid down as an apparently uniform deposit and is left aerobically at room temperature, concentric (Liesegang) rings often appear. These are so characteristic that the specific nature of the precipitate is established beyond doubt (Figs. 1, 2, and 3). They form much more quickly and more readily than the similar rings already described and illustrated in the haloes that are formed when an antibacterial serum against smooth strains of pneumococcus or group 1 meningococcus is incorporated in the agar (Petrie, 1932). A striking feature of the rings in the anaerobic haloes is the fact that, though the margin of the colony may be wavy or irregular, the circular zones give the impression of having been drawn with compasses. Two or three colonies on a spread plate may be seen to be enclosed within a double ring, or a bar of growth may show a double contour in the precipitate extending from its margin.

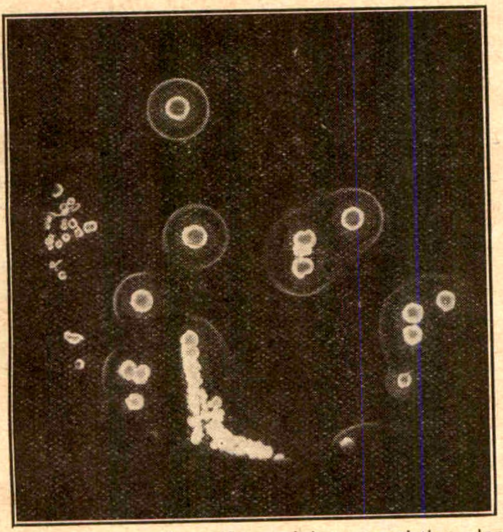

Fig. 1.—Shows rings of specific precipitate round the colonies of *Cl. welchii* on an agar plate containing *Cl. welchii* antitoxin.

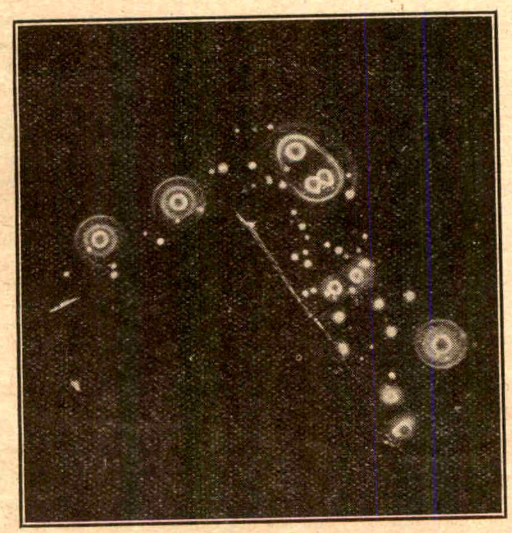

Fig. 2.—Shows rings of specific precipitate round the colonies of *Cl. septicum* on an agar plate containing *Cl. septicum* antitoxin.

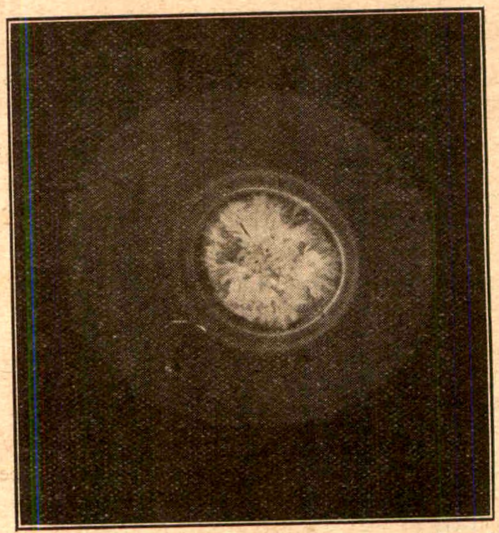

Fig. 3.—Shows rings of specific precipitate round a colony of *Cl. oedematiens* implanted on an agar plate containing *Cl. oedematiens* antitoxin.

The breadth and also the density of the rings in a particular halo often vary. Thus one of the best specimens so far obtained was observed after three weeks at room temperature round a colony (8 × 8 mm.) of *Cl. oedematiens* on agar which contained 75 I.U. of *Cl. oedematiens* antitoxin per c.cm. of the medium. Here there were four rings of precipitate separated by four clear zones. The innermost zone of precipitate was close to the colony but separated from it by a narrow clear space: this zone was narrow (0.5 mm. across) and of such a density as to appear white; then followed a clear zone of 0.5 mm.; then a zone of precipitate of 1 mm., showing a central groove as if about to split and of moderate density; then a clear zone of 1 mm.; next, a zone of precipitate of 1 mm. and of slight density; next, a clear zone of 2 mm.; and, lastly, a zone of precipitate of 1.5 mm. and with the least density of all. The measurements are approximate. A similar picture was given by a colony of *Cl. tetani* (type 1) when grown on a medium containing tetanus antitoxin.

The concentration of the antitoxin, expressed as I.U. per c.cm. of the medium, influences the extent and the density of the precipitate at an early stage of its development. Thus both an excess and also a suboptimal concentration of antitoxin may inhibit the reaction, in accordance with the fact that an excess of either of the reacting substances in the ordinary flocculation test brings about solution of the floccules. This no doubt explains why a narrow clear zone immediately adjoining the colony margin invariably intervenes between the colony and the precipitate, since the concentration of the toxin per unit-volume of medium is presumably highest in this region.

The most likely explanation, in our view, for the appearance of concentric zones is that the forces which combine to build up the framework of molecular aggregates as a uniform deposit to the naked eye are not in equilibrium, and that at a later stage stresses or strains in the structure result in condensation of the precipitate in the form of annular zones separated by clear zones. The remarkable symmetry of the concentric zones is evidence that the molecular aggregates which constitute the toxin-antitoxin precipitate within the semi-rigid matrix of the agar gel are disposed in an ordered arrangement and that the forces controlling them are in equilibrium. When the precipitate shows little tendency, even after a prolonged interval, to form multiple annular zones—as, for example, the diphtheria toxin-antitoxin halo—the density seems to increase from the margin of the colony to the outer margin of the halo, which appears as a dense ring and which may be surrounded by an extremely tenuous precipitate of considerable breadth, detectable when photographed but not apparent to the naked eye. This variety in its final form also gives the impression of representing a stage of stable equilibrium. The technique may prove to be useful for the study of periodic structures in general and of the physico-chemical basis of the toxin-antitoxin reaction.

Optimal Conditions for Production of Specific Haloes

The need for using a medium which is favourable for toxin production has been indicated by finding that ordinary agar and peptic digest agar are less suitable than the media recommended here. A natural (unconcentrated) antitoxic serum appears to give better results than a salt-concentrated antitoxin or a purified antitoxin as obtained by the pepsin process. The concentration of the antitoxin in the medium, as already stated, is an important factor. In our experience an amount equivalent to 4 to 8 I.U. per c.cm. of the medium gives good results for each of the three strains of anaerobe tested by us, but a smaller amount may prove to be better adapted to less toxigenic strains met with in field work.

When the plates are removed from the anaerobic jar after 24 or 48 hours they may show no sign of a precipitate, but if kept at room temperature aerobically a halo will appear and Liesegang rings may develop. This observation merely proves that toxin had diffused from the colony before its interaction with antitoxin had become manifest as a precipitate. The presence of formalin vapour does not inhibit the development of the reaction.

General Observations on the Method

The ease with which the reaction is obtained is fortunately in the order of the relative frequency and importance, as causal agents of gas gangrene, of the three anaerobes—namely, *Cl. welchii*, *Cl. septicum*, and *Cl. oedematiens*—and may depend upon the rate and vigour of the surface growth of each species on agar plates. The precipitate formed by *Cl. welchii* can be seen after 24 hours' anaerobic incubation. Until experience of the method has been gained it is advisable to keep the plates, after adequate growth has been obtained anaerobically, for a week or 10 days at room temperature aerobically in order to trace the sequence of changes in the haloes.

The method has probably a considerable advantage over those used hitherto, since the association of other bacteria in the colony will not exert a deleterious influence upon the formation of the specific precipitate so long as the toxin of the clostridium remains unaffected by metabolites liberated by the contaminants. As is well known, much of the confusion in defining and specifying the characters of the pathogenic anaerobes by determining their biochemical activities was caused in the past by the presence of unsuspected bacterial symbionts in cultures that were apparently pure. Obviously the method will fail when non-toxigenic colonies or strains appear on the plates, but from a practical point of view in relation to gas gangrene this result is not of serious moment, and is indeed an advantage.

Alternative Applications of the Method

The reaction has also been obtained in a column of agar in a test-tube inoculated on the surface with a culture of *Cl. welchii*; the homologous antitoxin had been added to the agar. The precipitate showed three zones, one above the other, to a depth of 4 mm. below the surface. There can be no doubt that a Seitz filtrate of a broth toxin prepared from the anaerobes in question will give a specific precipitate when superposed on a column of agar containing the corresponding antitoxin. When the toxin molecules have diffused into the agar, precipitation will take place either uniformly or in zones (Brown, 1940).

When the requisite apparatus for obtaining surface growths on agar plates in strictly anaerobic conditions is not available, a modified technique of this kind is worth a trial for detecting toxins in mixed cultures, and we suggest the following procedure.

Employ suitable selective methods to encourage the growth of each of the anaerobes sought for in the primary material, such as wound exudate. Subculture into a separate meat-broth tube or small flask of the Robertson type, but modified, as explained above, to favour toxin production of the corresponding anaerobe. Grow for 48 hours, filter through a Seitz disk, pipette the filtrate of each culture in a suitable amount on the top of a column of 2.5% saline agar containing 8 I.U. of the corresponding antitoxin per c.cm. of the medium, keep the preparation for one day or more at room temperature, and note whether a precipitate appears in due course. The addition of ascorbic acid to the fluid media during the enrichment process will favour both growth and toxin production.

This simplified procedure may not, however, always succeed, owing to destruction of the specific toxin by proteolysis, or from other adverse conditions induced by the accompanying contaminants. There has, as yet, been no opportunity of testing whether the method is a practicable one for determining the presence of one or more of the pathogenic anaerobes in the exudates of gas gangrene.

When the usual methods of obtaining effective anaerobiosis cannot be applied, the device recommended by Cruickshank and Macdonald (1942) may be adapted to our method and given a trial. These authors grow the inoculum on the surface of an ascorbic-acid–agar medium, superpose a sterile cellophane disk, and pour a layer of the same agar over the cellophane. The original account should be consulted for further details.

Specificity of the Reaction

There can be little doubt that the reaction is a highly specific one. Controls with normal horse serum and with the heterologous antitoxins have been negative. With our present knowledge of these toxins it can be asserted with confidence that when the test is positive the identification of the bacterium needs no support from any other differential character, such as its proteolytic or saccharolytic activities or its pathogenic action in susceptible experimental animals.

The Method as Applied to Investigation of Anaerobic Flora of Wounds and to Diagnosis of Gas Gangrene

The observations recorded here are based on one toxigenic strain of each of the three clostridia—namely, those which are used in this Institute for the routine production of the toxins intended for the immunization of horses. A limited number of comparative observations on halo production by the highly toxigenic Park-Williams No. 8 strain of *C. diphtheriae* and by weakly toxigenic strains—one gravis and two mitis cultures—when implanted on the same plate containing diphtheria antitoxin, showed that the gravis and mitis colonies produced haloes, although the precipitate took longer to form than that which was seen round the No. 8 colony; this result may be significant in the present connexion as indicating that the reaction has a fairly elastic range, provided that time is given for it to mature. Moreover, in a series of agar plates containing varying amounts of *oedematiens* antitoxin good haloes appeared within a range of which the extremes represented 7 and 70 I.U. per c.cm. of the medium, although in some of the plates the reaction was considerably delayed. If 8 I.U. of the antitoxin per c.cm. of the medium should prove to be an excessive amount, 4 units, 2 units, or 1 unit or less per c.cm. may readily be substituted by preparing successive dilutions of a portion of the antitoxin solution with an equal volume of sterile broth and adding 1 c.cm. of the dilution so prepared to the melted agar.

We hope that workers in Army and civilian laboratories who have opportunities of examining severe wounds will give the method a trial and thus help in defining its sphere of usefulness.

Summary

A method of identifying the three chief pathogenic clostridia met with in gas gangrene, by means of specific precipitation resulting from a toxin-antitoxin reaction round the colonies on agar plates, has been described. The appearances presented, and particularly the formation of Liesegang rings, are so characteristic as to leave no doubt of the identity of the associated bacterial species.

Our best thanks are due to Mr. J. Smiles of the National Institute for Medical Research for photographing agar plates illustrating the features of the specific precipitates.

TRICHLORETHYLENE ANAESTHESIA IN PLASTIC SURGERY

BY

RODERICK A. GORDON, B.Sc., M.D., D.A.
Major, R.C.A.M.C.

AND

R. P. W. SHACKLETON, M.R.C.S., L.R.C.P., D.A.

Striker *et al.* in 1935, and more recently Hewer (1942), have reported very favourably on the use of trichlorethylene as an agent for general anaesthesia. From these reports it appeared that this drug would have definite advantages when employed for anaesthesia in plastic surgery. These advantages were: (1) adequate analgesia in light planes of anaesthesia; (2) no increase in bleeding due to the anaesthetic agent; (3) minimal irritation of the respiratory tract; (4) freedom from post-anaesthetic vomiting; and (5) freedom from explosion hazard. We decided to test the drug on a series of 200 cases. Our experience led us to abandon its use after 100 cases.

Age and Type of Patients

The average age of the patients in this series was 29 years. The youngest was 10 years old, the oldest 65; 50 were between 19 and 40; 4 were under 19, and 46 were over 40. With 13 exceptions these patients were Class A anaesthetic risks. These 13 were considered fair risks, and the majority of them were not regarded as Class A risks only because of the presence of blood in the airway due to recent facial injuries.

Premedication.—Each patient received omnopon gr. 1/3 and scopolamine gr. 1/150 before operation. This premedication was ordered for three-quarters of an hour or one hour before the time scheduled for operation. In 9 cases it was actually given at periods up to two hours before induction, owing to alterations or delays in the operation schedule.

Induction

All patients but one were induced by the intravenous administration of sodium pentothal in 5% solution (Table I).

TABLE I.—*Induction and Maintenance*

Agents Used	No. of Cases
Pentothal, N_2O, and trilene	33
Pentothal, cyclopropane, and trilene	1
Pentothal, trilene, and O_2	65
Trilene and oxygen	1

The average dose given was slightly under 0.5 g. Thirty-three patients had nitrous oxide and oxygen, with trichlorethylene added. One had cyclopropane added during the induction. One patient was induced and maintained throughout with trichlorethylene and oxygen alone. The remainder had trichlorethylene and oxygen only, after the pentothal induction. The average amount of trichlorethylene used was 5.5 c.cm. per hour of anaesthesia and 7.4 c.cm. per patient. The preparation employed was that marketed under the name "trilene" and packed in glass-stoppered amber bottles for use in anaesthesia.

With two exceptions the nitrous oxide–trichlorethylene inductions were smooth, but somewhat more prolonged than we usually expect with ether, using a similar technique. Owing to the effect of the drug on respiration we found it difficult to evaluate the level of anaesthesia. Induction with trichlorethylene and oxygen alone, following pentothal, is prolonged, and often the robust patient recovered from his dose of pentothal rapidly enough to provide some excitement in the second stage. The one patient induced with trichlorethylene and oxygen without previous pentothal had profuse salivation and a very violent second stage.

In all instances we used closed-system anaesthesia of the circle type, with carbon dioxide absorption. In 97 cases the trichlorethylene was administered from a vaporizing bottle containing a wick and placed in the rebreathing circuit. In three a drip vaporizer outside the circuit was used. This last method proved unsatisfactory because of the low volatility of the agent. In 76 cases the anaesthetic was administered through a Magill endotracheal tube.

Effects on Respiration

The respiratory rate was increased in all but 16 patients (Table II). With the increase in rate there was in all cases a decrease in respiratory excursion. Five patients achieved respiratory rates of over 60 a minute at a stage of anaesthesia corresponding to the second plane of the third stage (Guedel). One of these patients had a respiratory rate of 80 a minute at this plane, and one robust subject had respiratory arrest. In the remainder the respiratory rate varied between 26 and 46 a minute. Except in the cases with extreme increase of respiratory rate no cyanosis was seen.

TABLE II.—*Respiratory Rate*

Rate per Minute	No. of Patients
18 to 25	16
26 to 46	78
60 to 80	5
Respiratory arrest	1

Cardiovascular Effects

The most constant effect on the cardiovascular system was the development of bradycardia (Table III). Forty-four patients had pulse rates under 60 a minute, 10 of these rates being between 40 and 50. Twenty-five had rates of between 60 and 70. The pulse rate in most cases varied inversely with the depth of anaesthesia, decreasing as the plane of anaesthesia was deepened. This decrease in pulse rate was associated with increase in respiratory rate. In several cases the respiratory rate equalled or exceeded the pulse rate.

TABLE III.—*Pulse Rate*

Peripheral Pulse	No. of Patients
Normal rate and rhythm	36
Irregularities	19
Bradycardia	44
Irregular during recovery	1

Nineteen patients had irregularities of the peripheral pulse during anaesthesia. With two exceptions these irregularities occurred with normal or accelerated pulse rates, and disappeared with the onset of bradycardia. In these two cases the peripheral pulse rate was irregular at slow rates, and a count of the rate at the cardiac apex showed a pulse deficit of about 30 beats, the apex beat also being irregular. These irregularities appear to be due to the occurrence of extrasystoles. One patient had an irregular pulse rate for 30 minutes during the post-anaesthetic recovery period.

One patient apparently had 3:1 heart-block shortly after induction, the pulse rate increasing suddenly from 40 to 120 a minute. Cyclopropane had been used during the induction of anaesthesia in this case.

During one operation the surgeon applied to a raw area a large pack soaked in 1:1,000 adrenaline solution. The pulse rate rapidly increased from 60 to 120, and became weak and "thready" in quality. It was at this point that inquiry by the anaesthetist revealed the presence of adrenaline in the pack. The pulse improved rapidly after its removal.

Blood pressure usually remained within normal limits. There was a general tendency for some increase in the systolic and pulse pressures in patients with bradycardia or normal pulse rates. In those with tachycardia or irregularities the blood pressure was very labile, and in one case it varied from 104/70 to 150/70 to 120/76 in a period of ten minutes. One young patient, aged 29, whose blood pressure before operation was 124/80, had a range from 160/100 to 240/160 during an anaesthesia lasting 65 minutes; throughout this time his pulse rate remained regular at 56 a minute.

Recovery

All patients recovered consciousness within a reasonable time after cessation of the anaesthetic, the average for the group being 35 minutes, and the longest two hours. Recovery time was roughly proportional to the duration of anaesthesia. With one exception there was no post-anaesthetic depression: this case was the one in which anaesthesia was induced and maintained by trichlorethylene–oxygen alone. The patient recovered consciousness in 90 minutes, but remained drowsy for 24 hours. Peripheral pulse, blood pressure, and respiration, however, were normal.

Complications

Vomiting.—Sixteen patients in this series vomited post-operatively. Of these, 10 vomited a small amount once only during the recovery period; 3 vomited once shortly after recovery; 1 vomited several times during the first 12 hours, and another during the first 36 hours; and the remaining patient vomited once 10 hours after the operation. There were no cases of persistent vomiting. Only one patient had recently taken food, and in this case there was no vomiting. Patients who did not vomit made no complaint of nausea after the anaesthetic.

Respiratory.—Seven patients had a history of recent respiratory infection. One of these had a post-anaesthetic pulmonary atelectasis, and another, with a history of chronic bronchitis, suffered an exacerbation of his complaint. These were the only subjects who showed any respiratory complication.

Discussion

We feel that, on the whole, the advantages of trichlorethylene as an anaesthetic agent for plastic surgery are far outweighed by its disadvantages. The only advantages of the use of the drug as an agent for surgical anaesthesia would seem to be freedom from explosion hazard, minimal irritation of the respiratory tract, and small cost. The disadvantages lie chiefly in its action on the cardiovascular and respiratory mechanisms, and its low volatility.

Although no facilities existed for electrocardiographic examination of this series of patients, it would appear from clinical observation that the drug has a definite action on the conducting mechanism of the heart, as well as a direct irritant or sensitizing effect on the myocardium. The relation of the bradycardia to the increase in respiratory rate and decrease in respiratory excursion suggests to us that part, at least, of the effect on the cardiovascular mechanism may have origin in the central nervous system. We consider that these cardio-respiratory effects require further elucidation before trichlorethylene is accepted as an anaesthetic agent for general use.

Summary

A series of 100 administrations of trichlorethylene for general anaesthesia in plastic surgery is reported.

The respiratory rate is greatly increased by the drug, and the respiratory excursion decreased. This result is associated with slowing of the cardiac rate as deeper planes of anaesthesia are attained. There is some instability of the systemic blood pressure. One case of heart-block occurred—after cyclopropane induction. Extrasystoles are frequent.

Post-anaesthetic recovery was good, and the only respiratory complications occurred in two patients who had a history of recent respiratory infection. Sixteen patients vomited after operation.

It is felt that the cardio-respiratory effects of trichlorethylene require further elucidation before this drug is accepted as an agent for general anaesthesia.

Speaking at a conference on venereal disease called by the Scottish Committee of the British Social Hygiene Council and held at Edinburgh on March 5, Mr. Thomas Johnston, Secretary of State, said that in Scotland last year there were nearly 5,000 recorded cases of fresh infection, apart from cases among Service personnel. In one Scottish town known infections had risen from 36 to 419. Existing treatment facilities were adequate for the increased number of cases, but it was most desirable that persons infected should come forward promptly and, what was no less important, should continue treatment until they were told by their doctors that it was safe to stop. About 40% of the patients who left centres did so before they were pronounced cured, and over 20% left before even completing a course of treatment. The Scottish Medical Advisory Committee had considered the increase in venereal disease at its first meeting and had advocated better sex education of young people, in which parents, school staffs, and family doctors could help. These diseases were more than a medical matter, and were, in fact, closely bound up with behaviour and with the ethical standards from which behaviour springs.

A NOTE ON TRICHLORETHYLENE ANAESTHESIA

BY

JAMES HAWORTH, M.B., Ch.B.
Anaesthetist, Burnley Victoria and Municipal Hospitals

AND

ALEXANDER DUFF, M.D., F.R.C.S.Ed.
Surgeon, Salisbury General Infirmary; formerly Resident Surgical Officer, Burnley Municipal Hospital

Since Hewer's (1941) suggestion that trichlorethylene might be a useful general anaesthetic a number of communications have appeared dealing with individual cases and difficulties, but we have seen only one report of a general investigation—that of Elam (1942). We venture, therefore, to offer the following observations. We have used the drug in the form of trilene in 306 cases, and have investigated such various points as could conveniently be done in ordinary hospital practice.

Technique of Administration

We have used the open mask and the machines of Shipway, Marrett, and the standard Boyle–Magill. We ultimately adopted the Boyle–Magill, and found that anaesthesia was well maintained with a flow of 3 to 4 litres of nitrous oxide and 1½ to 2 litres of oxygen per minute, the surface of the trilene in the chloroform bottle being faintly ruffled. There was partial rebreathing but no tension on the spring of the outlet valve. Using this method, surgical anaesthesia was induced in 7 to 11 minutes and maintained on a consumption of 1 drachm of trilene in 5 minutes during short anaesthesias or 1 oz. an hour for prolonged administrations.

Type of Anaesthesia

Induction.—In 22 of 143 cases (15%) there was a little struggling during the second stage. The patients who struggled were nervous women rather than plethoric men.

Relaxation.—This was much less than with chloroform, ether, or gas–ether anaesthesia. In 15 of 53 abdominal cases (28%) anaesthesia could not be pushed beyond plane 1 of stage 3, and resort was had to ether. This figure does not include a number of cases in which our colleagues bore with less relaxation than is generally considered desirable, and we take this opportunity of gratefully acknowledging their forbearance.

Cumulative Effect.—This is reflected in the relatively smaller quantity required in long administrations, already referred to.

Mode of Action

The drug appears to act by virtue of its solution in the blood and action on the central nervous system. We noticed that physical measures designed to increase the amount taken up by the body, over and above that obtained by the technique already described, had no influence whatever on the rate of induction or on the depth of anaesthesia obtained. These measures included heating the trilene with the water-bath designed for ether, bubbling the oxygen through the fluid instead of blowing across the surface, and increasing the tension on the outlet valve. The sole results were that anoxaemia was produced and that trilene was wasted.

We conclude, therefore, that overdosage from presenting too high a concentration of vapour is not the danger it is with chloroform, and that an ordinary skilled anaesthetist will produce the deepest anaesthesia possible in about 10 minutes, after which further efforts at securing relaxation are useless.

Effects of Trilene Administration

Respiratory System.—No salivation or irritation was noticed. Tachypnoea was troublesome in many cases. In 79 of 104 cases the respiration rate was over 40 after the patient had settled down. Rates of 60 a minute and over were often recorded.

Circulatory System.—Blood-pressure observations showed practically no change in the first half-hour and a slight fall thereafter. In a few of the longer administrations (one hour or more) the systolic pressure became irregular, varying up to 10 mm. Hg between beats.

Primary Syncope.—We had one fatal case of this in a girl aged 3 with some history of bronchitis; she was being anaesthetized for a hernia operation. The case resembled in every way the well-known primary syncope of chloroform anaesthesia, and we attribute this to the same mechanism of vagal inhibition.

Sugar Metabolism.—We were able to have blood-sugar estimations in only 3 cases. In each there was a rise after 30 to 45 minutes, but much less than that recorded for chloroform or ether by Hewer (1939). Acetone was found in the urine on the morning following operation in 23 of 68 cases, in none of which had ether been used. This is in striking contrast to Hewer's report that he did not find acetonuria in any case at all.

Post-operative Vomiting.—This was absent in 52 out of 80 cases, and slight in the remaining 28.

Use in Midwifery.—We have administered trilene on an open mask in two normal cases. The cumulative effect was especially noticeable, so that after about 15 minutes analgesia was produced with only the occasional addition of a few drops to the mask.

Conclusions

1. The action of trilene resembles that of chloroform.
2. The limited solubility of the drug in the body fluids renders overdosage very unlikely, and also satisfactory anaesthesia difficult in many cases.
3. Primary syncope is a danger, as with chloroform.
4. Trilene is indicated: (*a*) when it is necessary to administer a non-inflammable anaesthetic by means of a machine—e.g., in diathermy operations on the throat or upper air passages; (*b*) when an adjuvant to gas–oxygen anaesthesia is required and ether is contraindicated.
5. Its use as an analgesic in midwifery deserves consideration.

N.B.—Since the above was written, Mr. Stowell (*British Medical Journal*, 1943, 1, 302) has pointed out that trilene is not suitable for operations with diathermy, since at 125° C. it decomposes, forming phosgene and hydrochloric acid.

Medical Memoranda

Fatal Poisoning by Methyl Salicylate Liniment

The following case is recorded because of the rarity of published cases of poisoning by lin. meth. sal., because the dangerous potentialities of this liniment as a poison are not fully appreciated, and because of the disastrous result of failing to carry out stomach lavage.

CASE HISTORY

The victim was a Sudanese servant aged 33, of medium height and weight and enjoying normal health. He drank lin. meth. sal. at about 2 30 p.m. on May 19, 1941, in the belief that it was alcohol. The amount of liniment drunk was not more than 4 oz., but it was taken at one gulp in an attempt to impress his friends who had previously sipped it and decided that it was unpalatable. The man rapidly became extremely ill, vomiting copiously and passing into a state of collapse, but, owing to the circumstances of the drinking and the belief of his friends that he was merely extremely drunk, no medical aid was summoned until 5 p.m., when the illness seemed more severe than it should have been. When seen at that time he was restless, fully conscious, able to talk freely and rationally, and did not appear to be in any pain (indeed he admitted that he had no pain), but he was much distressed. He had vomited frequently, and vomit seen later was a clear yellow fluid with a little mucus, smelling strongly of wintergreen. The tongue was moist; there was no evidence of corrosion on the lips, tongue, throat, or buccal mucous membranes. The breath smelt strongly of lin. meth. sal., but breathing was normal. The skin was extremely cold to the touch and a few beads of perspiration stood on his forehead. His pulse was regular, of good volume, and rate 100. Pupils were equal. The abdomen was soft and there was no evidence of pain or tenderness

The stomach was not washed out, but copious fluids were ordered with sodium bicarbonate by the mouth and, later, a mixture of milk and water. This he took well, but he vomited two or three times during the following few hours, though his general condition was improving when he was seen at 6 p m. and again at 7 p.m. Later he complained of noises in the ears, but at 9 p.m. he was feeling very much better, his pulse rate was 80, vomiting had ceased, and he was sitting up in bed smoking a cigarette. During the night he passed water twice. However, the following morning when seen at 7.45 a.m. his condition had greatly deteriorated. His pulse was 90, regular, and of fair volume, the skin was again cold and clammy, and the tongue moist but slightly furred. His breathing, however, was noisy, laboured, and increased in rate, and he was taking very little interest in his surroundings. Two hours later his condition was still worse: respirations 32, temperature 97° F., pulse thready and accelerated to a rate of 112. Fine crepitations were now audible at both lung bases. A white blood count showed a polymorphonuclear leucocytosis with a total count of only 2,400. At 11 a.m. the pulse was 122 and very feeble, respirations 32, skin still cold, and he appeared very gravely ill. The lung signs had proceeded apace, and in addition to the crepitations at the right base there was impairment of the percussion note at the left base with bronchial type of breath sounds. In short, the signs of lobar consolidation were now evident. Sulphapyridine 5 g. was given (10 tablets) and nikethamide (coramine) and strychnine injected; the sulphapyridine was to be continued 1 g. four-hourly. By 1 p.m. the patient was delirious and so restless that morphine 1/6 gr. was required to quiet him. This subdued his restlessness but his condition did not improve, and at 2.45 p m. on May 20 he died; almost exactly twenty-four hours after drinking the liniment.

COMMENT

It seems likely that the fatal issue was not directly due to the toxic effect of lin. meth. sal. *per se*, since there was an initial period of acute illness due to traumatic gastritis, followed by a well-marked period of recovery in spite of evidence of absorption of the poison, indicated by the noises in the ears. It almost seemed as if the danger was past, but the recovery was succeeded by the rapid development within a few hours of signs of lung consolidation. This lung involvement was particularly impressive and definite. It is possible that in the course of vomiting in a somewhat collapsed condition, some of the regurgitated liniment may have been inspired and passed to the lungs, acting as an irritant, and thus facilitating, if not actually causing, the onset of basal consolidation, much in the same way as the irritant poison gases such as phosgene and chlorine act. I feel strongly that gastric lavage would have prevented this complication. The chief reason it was not adopted was that we were misled as to the facts at the time; the real facts only came out at the subsequent inquiry. Finally, one clinical observation was quite striking—the extreme coldness of the skin at the time of the first examination.

I am indebted to Lieut.-Col. T. Scott Law, R.A.M.C., for permission to publish these notes, and to Major J. Mackay Dick, R.A.M.C, for his help in connexion with the case.

ERIC TOWNSEND, M.D., D.P.H.,
Captain, R A.M C.

Tetanus in the Puerperium

Dr. A. T. Duncan's case recorded in the *Journal* of Oct. 10, 1942 (p. 426), recalls to my mind a case of tetanus in the puerperium which occurred in my practice 28 years ago and proved fatal. The chief interest of that case lay in its unexpected origin.

The patient, a 2-para, was a rather fragile and delicate young lady of about 25. Six days before labour occurred she complained of pain and slight swelling over the left upper jaw, obviously due to carious teeth, which had completely cleared up by the time of her confinement. Labour was somewhat protracted and difficult owing to occipito-posterior presentation; forceps were used, and there was a little difficulty in expressing the placenta owing apparently to some adhesion of the membranes. After the confinement the patient ran a temperature (under 100°) for ten days; it then dropped to and remained at normal.

On the 12th day she complained of right-sided trismus with slight pain over the right jaw. There was no swelling, but slight tenderness was felt on pressure over the upper and lower right molars. On the following day right-sided trismus persisted and, in addition, there was slight retraction of the neck. Next morning the temperature was still normal, but there was decided swelling over the right lower jaw, and difficulty in swallowing had developed. Later in the day the temperature rose to 100°. Under chloroform forcible opening of the jaw revealed an abscess of the lower right wisdom tooth with a few drops of pus escaping from the surrounding gum. The tooth was extracted. The temperature dropped to normal and absence of trismus was noted for the next two hours, when it reappeared and remained.

On the 15th day an attempt to swallow medicine produced a very severe tetanic spasm of the throat and neck muscles, in which the patient became black in the face and ceased to breathe, while the arms were stiff and facial contraction occurred. A succession of these severe attacks continued at fairly frequent intervals during that day and the following night, and proved fatal next morning. Dr. Mervyn Gordon, bacteriologist to St. Bartholomew's Hospital, happened to be staying in the town and kindly saw the patient with me. At his suggestion the offending wisdom tooth was sent up to St. Bart's laboratory, and in the abscess at the root of the tooth the tetanus bacillus was definitely found

Consideration as to how the bacillus had reached the tooth led to further inquiry, when it was elicited that the patient was fond of apples and bananas, and had recently been seen to break into the peel with her teeth instead of using a knife or other means.

Penzance. E. C. EDWARDS, M.D.

Reviews

RHINO-LARYNGOLOGY

Surgery of the Nose and Throat. Edited by John Devereux Kernan, M.D. (Pp. 701; illustrated. $15.00 or £3 10s.) New York and Edinburgh: Thomas Nelson and Sons. 1942.

Surgery of the Nose and Throat, edited by Dr. John Devereux Kernan, is another of the Nelson Loose-leaf Series, and is the work of nine contributors, including the editor. The surgery of the nose and its accessory sinuses is described by Harry Neivert in a complete and satisfying fashion. The physiology of the nose and the work of Proetz receive attention, and the need for a conservative outlook is recognized. A much shorter article on the reconstructive surgery of the nose, by James Barrett Brown, follows. This is excellent and well illustrated, though there is a little overlapping with the previous chapter. The surgery of the oropharynx and nasopharynx, by George Renfrew Brighton, is concerned almost exclusively with the tonsils and the local complications which arise from tonsillitis. Adenoids are included, and with this limitation a good description with an anatomical basis is given. The surgery of non-malignant conditions of the larynx is described by John Devereux Kernan and Arthur J. Cracovaner. This portion is comparatively short, occupying 137 pages, including many illustrations; but it is well designed, and ends with a description of laryngofissure. It is full of information on every relevant matter except cancer, to which a separate chapter by Hayes Martin is devoted. This chapter includes the pathology, surgery, and radiological treatment of cancer of the larynx. It is the least satisfactory part of the book, and the attempt by one writer to describe all three aspects of the subject has not produced a convincing description of any of them. The author takes it as an axiom that all extrinsic cancer is inoperable, a proposition which is refuted in the following chapter on malignant tumours of the pharynx, by Henry B. Orton. Chevalier L. Jackson contributes a short chapter on bronchoscopy—an excellent account which does not attempt to delve deeply into the technical details of the manipulative and instrumental manœuvres for removing foreign bodies, but is a useful general survey. The masterpiece is reserved for the end. This is Chapter VIII, on the histopathology of the nose and throat, by Andrew A. Eggston. The normal histology of these regions is first described, and is followed by a short account of the physiology. Then comes a full description of all the pathological processes which occur, the portion dealing with tumours being especially instructive. This section forms a unique feature of the book, which is generously illustrated throughout.

DIABETES MELLITUS

Diabetes Mellitus. By Zolton T. Wirtschafter, M.D., and Morton Korenberg, M.D. A William Wood Book. (Pp. 186. $2.50 or 14s.) Baltimore: The Williams and Wilkins Company; London: Baillière, Tindall and Cox. 1942.

This is a difficult book to review on account of its wide and vague scope, almost entirely theoretical. Perhaps it is fairest to let the authors' preface speak for itself. "This monograph is written for the individual who asks what is the nature of the processes that characterize disease, and what is the purpose, and the accomplishable in the treatment of diabetes mellitus. . . . Only a thorough summary of the fundamental principles involved in the metabolism of carbohydrates, proteins, fats, minerals, vitamins, and endocrines in diabetes mellitus can make one independent of 'rule of the thumb' procedures. This review of the extensive literature of carbohydrate metabolism in health and disease can serve no better purpose than to emphasize the pitfalls and dangers of mechanical methods of diagnosis and treatment of diabetes mellitus."

The book devotes successive chapters to all the main physiological aspects and describes most of the recent experimental work and views—not fully enough to serve as a complete work of reference but in an interesting way, especially as regards glycogenesis, ketosis, and acid-base balance, and the vitamins. At the end of the book the authors leave theory and experiments to include two chapters on general treatment and on diabetic coma, too brief to be of much practical value. For coma they recommend glucose and bicarbonate intravenously, normal saline (3 litres) subcutaneously, and 25 units of insulin, 50 mg. of thiamin, and 100 mg. of ascorbic acid intravenously, the last three to be continued intravenously every hour in half-doses. This is a novelty which is neither explained nor justified, and the advice to massage the site of insulin injection seems superfluous with administration by vein.

CIVILIAN HEALTH IN WARTIME

Civilian Health in Wartime. By Francis R. Dieuaide, M.D., Associate Professor of Medicine, Harvard Medical School. (Pp. 328. $2.50.) Cambridge, Mass.: Harvard University Press; London: Oxford University Press. 1942.

Of recent years there has perhaps been a tendency to regard health as precariously balanced on a razor edge, overlooking the fact that, given good conditions of environment, the human body, as W. B. Cannon pointed out, has extraordinarily wide powers of readjustment. But total war changes environment, occupation, and diet for nearly everyone, so that external re-adjustments are called for. These Dr. Dieuaide of Harvard, in *Civilian Health in Wartime*, has tried to explain to the general public in simple, sensible terms. Naturally he deals with the subject from the American point of view, and many of the statistics given do not apply to this country. At the same time he draws many illustrations from British experiences, and in terms gratifying to our national pride. Reading between the lines, however, we can see that he thinks his own countrymen are still far from realizing the implications of modern warfare as it affects the civilian. Until the war of 1914-18 deaths from disease outnumbered those from wounds; with the rise of preventive medicine and the increase of mechanization the balance has swung the other way, so that "only two infectious diseases, tuberculosis and pneumonia, cause more deaths each year than automobiles." This may be related to the fact that in America families spend 4% of their income for medical care, which is "less than for automobiles, which take over 6%." There are a number of interesting remarks in the course of his argument, such as those on excessive hours of work. "English experience in 1914-18 provides pertinent data. When the weekly hours of male war workers were cut from 63 to 54, time lost for sickness fell by 43%. Among women there was a saving of 52% when hours of work were changed from 62 to 54." This time we seem in danger of forgetting our own former experience. There are some sensible remarks on the superior adaptability shown by women's clothing compared with the unreformed state of masculine attire; and there are still not a few who will agree that "the medical profession has sound reasons for looking askance at proposals which even vaguely suggest a huge national service with a cabinet minister at the top [and] a hierarchy of officials." An excellent epilogue on morale completes a book full of common sense.

Notes on Books

On the death of PAUL SCHILDER, the Society for Psychotherapy and Psychopathology, New York, of which he was the founder and first president, arranged for the editing and publication of his work *Goals and Desires of Man.* It therefore lacks the advantage of a final revision by the author. A convinced Freudian, it is significant to observe that he departed from strict orthodoxy on such matters as the "death wish" and aggression while holding to the Oedipus complex in all its implications, though not a few Freudians have minimized the latter doctrine rather than the former in recent years. There are some interesting analogies drawn from biology, but the psychological studies of Charlotte Brontë, the Duke of Wellington, and Pierpont Morgan are entirely unilluminating. Indeed, the book professes a profundity which it does not really possess. Surely it does not require a prolonged discussion to reach the conclusion that "we cannot evade the assumption that human beings have different gifts," even when backed up by the startling statement that "we have learned in the past years that artistic gifts are almost ubiquitous"! The verbose, heavy-footed style does not add to the attractiveness of a book which, despite its earnest endeavour to put forward a point of view, we found disappointing. It is published in New York at $4.00 by the Columbia University Press, and in London at 26s. 6d. by the Oxford University Press.

Every teacher and student of first aid should possess a copy of *Training in First Aid for Civil Defence Purposes,* A.R.P. Handbook No. 10, a second edition of which is now available (H.M. Stationery Office, price 6d.). It contains some very sound advice—for example, that indoor and outdoor practices should be held first in daylight and then in the dark. Nothing could be better than the summary of general principles of first aid—that in all cases the first consideration is to save life, the second to deal with shock, the third to prevent aggravation of the injuries, and the fourth to arrange for rapid removal of the casualty. There is an excellent account of the use of faked casualties in teaching. It would be as well to avoid the use of such terms as " compound " for " open " fracture and fracture of the " leg " when fracture of the femur is intended. The use of webbing bands (now included in first-aid equipment) for carrying casualties is described and good diagrams are included, but in suggesting material for improvised splints laths from venetian blinds should not come first. Direct digital pressure upon the actual arterial bleeding point is not mentioned, but the use and abuse of a tourniquet are discussed. The handbook states that in all cases of abdominal wounds shock will be extreme; this statement is somewhat sweeping, for in the absence of such shock an abdominal wound might be overlooked. Nevertheless, this handbook is extremely useful and right up to date.

That a book has reached its ninth edition is sufficient evidence that its subject-matter (repeatedly brought up to date) is sound and that it satisfies a demand from a discriminating public. A careful reading of *Food, Health, Vitamins*, by R. H. A. PLIMMER, D.Sc., and VIOLET G. PLIMMER, confirms this to the full. As the authors state in their preface to this edition, they have discarded " what once seemed good " and embodied " what now proves best." Additions to scientific knowledge of the vitamins and their action on the human body are explained in terms understandable by the non-scientific reader, and excellent suggestions are given for making the best of the wartime diet. The book deserves a better binding, even in wartime. It is published by Longmans, Green and Co. at 7s. 6d.

Preparations and Appliances

A SIMPLE METHOD OF SERUM TRANSFUSION IN THE FIELD

Squadron Leader J. C. McC. BROWNE, M.B., B.S., R.A.F.V.R., writes :

The value of early serum infusion in varying concentrations in cases of shock and exsanguination is now well established. The apparatus here described is designed to facilitate the giving of blood serum to a wounded man under field conditions. It is especially applicable to cases resulting from aircraft crashes in isolated places where there has been delay in reaching the scene or where immediate evacuation to a near-by hospital is not possible. The apparatus (Fig. 1) consists of: (*a*) a standard bottle of dried serum fitted with a rubber cap ; (*b*) a 500-c.cm. bottle of sterile fractionally distilled water, with a rubber cap ; (*c*) a small hand-pressure bulb such as is used on a nasal spray, with two valves ; (*d*) a piece of rubber tubing 15 in. long ; (*e*) four No. 18 gauge needles ; (*f*) a glass adaptor ; (*g*) 1 oz. of tr. iodi mitis ; (*h*) an air filter consisting of a glass bulb filled with cotton-wool. All four needles are protected by packing in glass tubes, and the rubber caps by a wax coating. The bulb, tubing, needles, and adaptor are wrapped in a towel and autoclaved. The entire apparatus when packed weighs 3 lb. 12 oz. and measures 9 in. × 8 in. × 4 in.

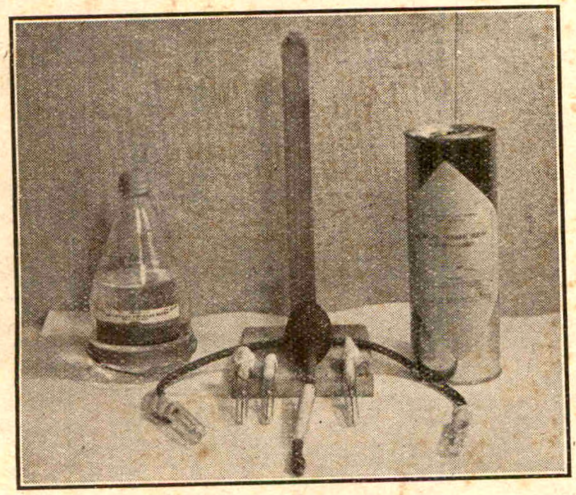

FIG. 1.—Apparatus laid out for use.

Procedure to Introduce Water into the Serum (Fig. 2).—The caps of the bottles are swabbed with iodine after removal of the wax, the cotton-wool plug from one of the tubes being used as a swab. One needle attached to the tubing by the adaptor is pushed just through the rubber cap of the water-bottle, and another on the other end of the tubing just through the cap of the serum-bottle. The third needle is also pushed well through the cap of the latter to allow escape of displaced air. The fourth needle is then pushed through the cap of the water-bottle and the filter and bulb are attached. The water-bottle is then inverted and air is pumped into it until the required amount of water has been displaced into the serum-bottle, which is then shaken until the dried blood serum is dissolved.

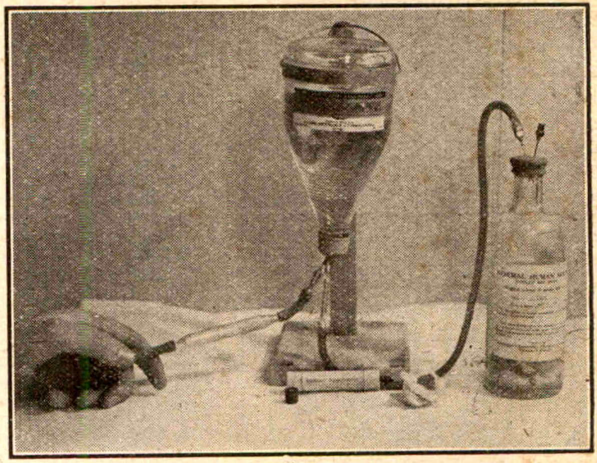

FIG. 2.—Introducing water into the serum.

Giving the Serum (Fig. 3).—The bulb and filter are transferred to the third needle (in the serum-bottle). The needle attached to the adaptor is removed from the water-bottle, detached, and inserted into the vein in the usual way. The serum-bottle is inverted and serum pumped out until all air is removed from the tube and adaptor, when the latter is attached to the needle. Serum can then be pumped into the vein.

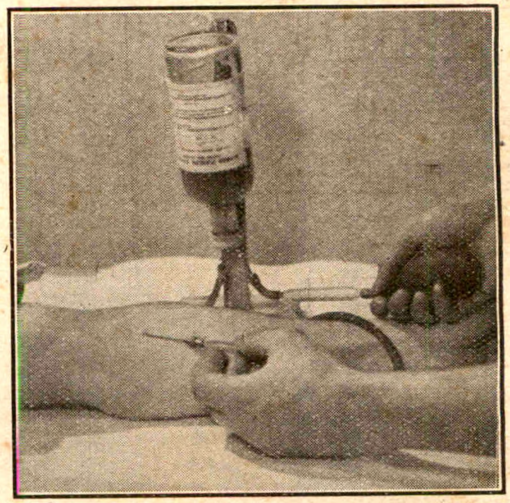

FIG. 3.—Giving the serum infusion.

The following details should be noted : (1) A filter to eliminate solid lumps of serum in the intravenous flow has not been found necessary. (2) In giving the serum it is important that the needle to which the bulb is attached is pushed through the cap to the hilt, the other needle being only *just* pushed through, as otherwise an air embolism may occur, due to bubbles of air passing direct from one needle to the other. (3) With the aid of a small collapsible support for the inverted bottle the whole operation can be carried out by a medical officer single-handed.

MAMMARY CANCER IN MICE

The rapid advances now being made in our knowledge of the aetiology of breast cancer in mice are exciting widespread interest, which is quite understandable if only because these tumours have been regarded as most typical examples of malignant neoplasms: they are carcinomas arising in glandular epithelium; they are not filterable, though they are transmissible from host to host indefinitely by means of cell grafts, a crucial test of malignancy; and they occur in mammals. The advances have become possible because special strains of mice have now been maintained so long by strict brother-by-sister mating—about 7 years is the necessary minimum—that practically all heterologous genes have been lost and closely related members of a strain are now almost as closely alike as identical twins. In some strains the incidence of cancer of the breast is uniformly high, in others uniformly low; and by such operations as cross-breeding and cross-fostering three major factors have been demonstrated co-operating in the production of these tumours. One factor is an inherited susceptibility; another is some specific element which ordinarily passes from mother to young in the milk; and another is the action of oestrogenic hormones on the mammary gland. Outstanding facts that have to be explained are conveniently illustrated in statements published by Bittner. He observed that in the high-cancer inbred mouse strain A the incidence of cancer of the breast is 96% in females which are allowed to breed freely, but is only 5% in those which are not allowed to breed at all. He observed also that, whilst in breeding females of strain A the incidence is, as just mentioned, 96% in those which have been suckled by their own strain A mothers, it is only 5% in those which have been suckled only on females of the low-cancer strain C 57 black; and, conversely, that in strain C 57 females which have been suckled only by their own strain C 57 mothers the incidence is only 0.5%, whereas it is up to 11% if suckling has been on strain A mothers. With other strains of mice the corresponding figures may be very different, but it would appear that in general the three-factor explanation holds good as a first approximation provided it be recognized that the different factors may vary very greatly in relative importance from strain to strain of mice. Much of the more recent work has been done in America, particularly by Bittner, Andervont, Little, and W. S. Murray, and a detailed knowledge of the present situation may be gathered from the many papers published in *Cancer Research* and in the *Journal of the National Cancer Institute*, both American publications. A comprehensive general review with an extensive bibliography has been published recently by Bittner.[1] All that can be usefully attempted here is a stocktaking statement of what appears to be the more important facts accumulated by workers of established reputation.

Existing special inbred strains of mice fall naturally into two main groups—high-cancer with characteristic incidences near 100%, and low-cancer with characteristic incidences around 2%. Low-cancer strains are of two types: those which, like strain C 57, are low because the individuals are so lacking in sensitivity that tumours develop only under exceptional circumstances, and those which, like strain C, are low simply because in them milk factor is wanting. Bittner has produced a substrain of this latter type, his Ax, by starting from a sensitive strain A female which had become non-cancerous because suckled on a low-cancer C 57 female. Mice of either of these two strains, Ax and C, can form the starting-point of permanent high-cancer lines provided they have been suckled on high-cancer females and so have acquired milk factor. How far significant hormonal features should be regarded as being ultimately only manifestations of genetically controlled hereditary strain characters is an open question. Hereditary susceptibility is a strain characteristic and is transmissible alike by both male and female parents. In Bittner's experiments with strains A and C 57 the mode of transmission was found indistinguishable from that of transmission by a single dominant Mendelian gene; but other workers, using other strains of mice, have found greater complexity. Andervont, for instance, found evidence that multiple genetic loci are involved when he showed that the degree of susceptibility varies with the strain of mouse: hybrids obtained by crossing high-cancer females of C3H strain with low-cancer males of strains I or C 57 or Y had incidences of 100%, 95%, and 71% respectively. Little found that in his mice susceptibility is influenced by several of the known genes. Hardly anything is known of how genetic constitution becomes manifest as susceptibility; whether it is through determination of the chromosomal constituents of mammary cells or by some less direct means.

Bittner has recently shown that by means of a high-speed centrifuge the milk factor can be spun down from extracts of lactating mammary gland, and he has reached the conclusion that very probably the milk factor is a colloid of high molecular weight and may be a virus. The milk factor certainly exhibits some of those qualities of living things which one usually associates with the presence of a virus. The milk may be frozen or dried without loss of potency. The factor is present in the milk of all high-cancer mice, and the fact that the milk remains unchanged in quality and potency from generation to generation indefinitely is taken as evidence that the milk factor must increase in amount, possibly by self-multiplication. The milk acts quantitatively over a certain range of dosage, maximum effect in high-cancer strain A, for example, being reached only when suckling has extended to some 24 hours or when some 2 c.cm. of milk has been given by mouth. Milk may differ in potency from one high-cancer strain to another, but the factor itself is not necessarily strictly strain-specific, since, for example, the milk factors obtained from foster mothers of the two strains C3H and A will both notably increase the incidence of breast cancer in strain C 57 mice. Milk factors, too, from different sources seem much alike in another respect, for none has been noticed producing its own histologically characteristic varieties of breast cancer. The factor is present in the milk of high-cancer strains during the whole lactation period, and mice are known to be susceptible to its influence up to the age of 4 to 5 weeks at least. A number of facts indicate that the milk factor can lie dormant for long periods and may even multiply without ever being associated with frankly cancerous tissue. In high-cancer strains, for instance, the earlier litters are born and receive potent milk long before their mothers reach the minimum cancer age, which is at about 5 months, and there is no indication that such transmission from first litter to first litter, generation to generation, cannot continue indefinitely. The few females of high-cancer strains which remain free from breast cancer to the end of their natural lives commonly transmit milk factor to their suckling young as effectively as other females of their strains. Also, in males of sensitive strains the milk factor commonly lies latent throughout life unless provoked to tumour-forming activity by prolonged administration of oestrone or similar substance. Practically nothing is known of what is happening to the milk factor during these long periods of apparent latency. There is evidence that the milk factor is recoverable from circulating blood and from spleen of high-cancer mice of pre-cancer age. When young females of high-cancer strain are compared with their own litter-mates which have been fostered on low-cancer females, and have therefore received no milk factor, it is found that the mammary gland shows a richer terminal arborization pattern. There is no evidence that milk factor leaves the body in significant quantity except in the milk. No decided infectious or contagious tendency has been observed in groups of mice living together, and when crosses are made between low-cancer females and high-cancer males continuous presence of the male parent makes no difference to the incidence, he cannot in any way transmit the milk factor he absorbed as a suckling.

---

[1] *Trans. Stud. Coll. Phys. Philadelphia*, 1941, 9, 129.

If the ovaries are removed whilst the mice are still very young, liability to develop cancer of the breast in later life is reduced. This suggests oestrogenic hormonal factors. The involvement of oestradiol, a natural ovarian hormone, is shown, for example, in the observation that if male mice of sensitive strain—which never develop breast cancers spontaneously—be treated with oestradiol or kindred substances over prolonged periods the incidence of mammary cancers becomes high, attaining in some strains the level of that found in the breeding females. Other constituents of the complex hormonal system of the body are also known to be involved, and there are associated changes in the pituitary gland and in the adrenals. The significant changes which take place in the mammary gland are in some way specific; the fully active lactating mammary gland is not one of the intermediate stages leading to cancer. Little describes how prolonged administration of oestrone produces a gradual hypertrophic change in the mammary gland and how this change progresses steadily until the fully cancerous condition is reached. In advanced stages the changes are patchy in distribution, for in some areas of the gland they proceed more rapidly than in others: in the early period of the frankly malignant condition a cancer may spread more by conversion of neighbouring cells than by multiplication of cells already malignant. Little's findings are remarkably like those described by Sir Robert Muir in his studies of cancer of the breast in women. In mice the milk factor is present in tumour tissue in considerable amounts, as can be shown by feeding tests. Testosterone has an action antagonistic to that of oestradiol, and will reduce the incidence of cancer of the breast if administration is started sufficiently early, but neither oestradiol nor testosterone will affect the growth of an established cancer.

Obviously the story is still incomplete. We cannot yet see clearly the significance which known facts have in relation to the aetiology of mouse tumours in general, or even whether they have significance in relation to all breast tumours of mice. Bittner thinks he has evidence of a second and much rarer type of breast cancer: one which is not generally distinguished from the common type, and which indeed is only peculiar, so far as is known, in the fact that its occurrence is not markedly correlated with capacity to transmit milk factor and produce cancer in the offspring. In considering possible indications for medical procedures in human beings it must be remembered that mankind is a very mixed stock and that the chances that a mother who is producing milk factor—if any ever do—should have a susceptible female child is more remote than among these special inbred strains of mice.

EXPERIMENTAL NEUROSES

No one who has observed the types of war neuroses that may follow exposure to stimuli that threaten danger can fail to be impressed by the similarity that exists, on the surface at least, between some of them and the phenomena of experimental neuroses in animals.[1] In both cases there is a stimulus which has a subsequent effect in producing a state of uneasiness. The human being exposed to air bombing, for example, becomes like the animal in the Pavlovian type of experiment—restless in the presence of anything that reminds him of the original stimulus, with insomnia, irritability, over-sensitiveness to stimuli (including jumping at noises, for example), altered social reactions (such as shyness), apprehensiveness, and visceral disturbances. The same tendencies to improve with a rest away from the scene of action or from the experimental laboratory, as the case may be, and to relapse on return to the old environment, are evident in both instances. The effect of rest, the greater susceptibility of certain individuals, and the relative inefficiency of sedative drugs are all similar. The possible importance of such observations, assuming—and it is still a large assumption—that the similarity is more than an apparent one, is this: that whereas it is necessary to postulate a motive or a wish to escape to account for the existence of symptoms depending on mental conflict, it becomes possible to conceive some symptomatic "neuroses" in fundamentally physical terms—i.e., as the expression of an uninhibitable excitation throughout the central nervous system. This is in accord with (*a*) the occurrence of neuroses after a certain period of time in people of sound morale, this being presumably a fatigue effect, since the first effect of fatigue is probably to loosen inhibition; (*b*) their greater tendency to occur in people of a certain temperament; (*c*) their occurrence in people in whom there is reason to suspect that their inhibitory processes are weak (e.g., certain obsessionals); (*d*) the failure of psychotherapy to do much for this type; (*e*) their specificity—e.g., a man may fly courageously but become extremely unhappy on the threat of air bombardment while on the ground.

There are risks in drawing parallels between dogs and men. It is well known that similar syndromes may have a very different pathology. There is little apparent resemblance between the differentiation of closely similar stimuli, which is the normal experimental condition in animal neuroses, and the frightening situations in which the fighting man finds himself; but, according to Gantt,[2] neuroses exactly similar to those set up by a difficult differentiation can be produced in dogs by exposure to fright. Man does not require to be frightened to develop the phenomena of fear. The "representative-imaginative" function of consciousness becomes the conditioned stimulus instead of the actual situation, so that in war neuroses considered even in this way there is already a psychological factor. It is already a psychoneurosis and not a pure neurosis—i.e., it is not simply a matter of a physical situation resulting in disturbance. But, after all, the same can be said of the experimental animal, in which waiting can also become a conditioned stimulus, as Liddell and Anderson have shown. A psychoneurosis in the strict sense of the term only exists when the individual makes use of the symptoms of physiological disturbance in a social way, either to disguise from himself that he is afraid or to escape from the dangerous situation.

[2] *Amer. J. Psychiat.*, 1942, 98, 475.

It seems possible, therefore, that certain neurotic syndromes in war may be explained without invoking conflict in the mental plane and without invoking motive either. This would be in harmony with another current observation—that individuals developing neuroses when in a Service do not by any means always, and perhaps not often, improve as a result of discharge into civil life. It has always been tempting to apply Pavlov's observations to human beings, but to do so has seemed sometimes too simple and sometimes too far-fetched. It is possible that too much reluctance has been exhibited in this regard in peacetime. Some clinicians[3] more daring than others have suggested that repeated feverish colds may depend on conditioned reflexes, and that certain cases of sensitivity to food have been similarly explained in preference to regarding them as real allergic reactions. Even some of the more definitely social neuroses (psychoneuroses in the proper sense) might be conceived in the same way. For example, Gardner[4] has described the case of a boy who was always in difficulty with the authorities and has suggested that this boy's reactions to people were conditioned by his early responses to his father. There is at least a field for speculation; and in the war neuroses we have something which more closely approaches the experimental situation, making speculation less speculative.

CAUSES OF BLINDNESS

Over 70,000 persons in England and Wales are certified blind; of all these only 8,000 to 9,000 are employed or employable. The problem of the blind is therefore not only a human but also an economic one. With the stricter system of certification that has been in vogue during the past 20 years or so a mass of valuable statistical data is now available, and an excellent analysis of the material seen in Glasgow and the south-west of Scotland during the period 1929-35 has been presented by a Mr. J. Marshall and Dr. H. E. Seiler.[5] The observations cover 3,219 persons, and show cataract and myopia to be the two commonest single causes of blindness, each accounting for about 16% of the total. Venereal disease comes third with 14%, and other causes of sepsis account for about 11%. Then comes glaucoma with about 9%, whilst congenital anomalies and abiotrophies are responsible for over 7%. Surprisingly enough, injury, even in such a highly industrialized area as that surveyed by the authors, accounts for only 6.4%, though this rises to over 10% if the cause of blindness as it affects the first eye is considered. A clearer picture of the disabling effect and economic importance of the various causes of blindness is obtained if they are considered in a different way. Thus, cataract, which comes highest in the list of causes, falls to the eighth place if "patient-years" are calculated from the duration of loss of sight for each cause and the number of cases in these categories. In this way the significance of injury and congenital anomalies increases considerably. The causes of blindness must also be viewed in relation to the main age groups. In the school period congenital syphilis and non-industrial injury predominate; acquired syphilis is the most important single cause in the age group 16 to 29 years; myopia, too, becomes significant in this particular age group. In the age group 30 to 49 years syphilis and myopia again predominate, and industrial injury, though important, does not rank so high as it does in the preceding age group. At the higher ages degenerative lesions (myopia, cataract, glaucoma, and vascular diseases) account for about 60% of the total. In the group of 70 years upwards cataract and glaucoma account for 67% of all cases. Generally speaking, all causes of blindness fall heavier on males, with the single exception of diabetes, where there was a significant excess for females. The relation of blindness to occupation varies, of course, with different regions. For Glasgow and the south-west of Scotland the incidence was outstandingly high in miners and quarry workers, with textile workers and metal workers next in frequency. A matter of some interest is the fact that myopia does not occur with any significant excess in the various occupations.

Studies of this kind reveal only too plainly that great gaps still exist in the prevention of blindness. It is gratifying to the surgeon to restore vision to an elderly patient suffering from cataract, but the social significance of preventive work in the younger age groups, though less dramatic, is far greater. The control of venereal disease, a reduction of industrial eye injury, a deeper understanding of the various inflammatory and degenerative conditions that lead to blindness are all problems that the ophthalmologist has to face.

BOVINE BRUCELLOSIS

The close relation of medical and veterinary sciences imposes on the medical man the duty of keeping in touch with advances in the control of animal diseases. At a recent discussion arranged by the Parliamentary and Scientific Committee on the compulsory pasteurization of milk Wilson[1] stated that an average of 5 to 10% of farms sent out milk containing tubercle bacilli, and 20 to 40% milk containing *Brucella abortus*—both infections deriving from diseased udders. In 1937 Brockington[2] estimated that three-fourths of the milch cows in this country would at any one time be found excreting one or more of the organisms, *M. tuberculosis*, *Br. abortus*, and haemolytic streptococcus, in virulent form. While this view may be an exaggeration, there can be no question about the extent and seriousness of the problem, which is, in the first instance, one of economics and animal husbandry. Efficient pasteurization of the milk supply is essential to ensure safety for the consumer, but this should be accompanied by other measures designed to obtain clean milk and to reduce the incidence of disease among dairy herds. Tuberculosis has received a good deal of attention as one of the chief wartime problems, but veterinary surgeons are also seriously concerned about contagious abortion, which causes considerable loss to farmers from abortion, infertility, and diminution in the milk yield. The true incidence of undulant fever (brucellosis) in man is uncertain owing to the number of undiagnosed cases and the probable large number of ambulatory or mild cases. A useful article on the clinical aspects of the disease was recently contributed to these columns by Dr. D. G. Leys.[3]

Contagious abortion presents unusual difficulties in diagnosis as well as eradication. Infection in animals would often appear to be light, and it may be many weeks or months before agglutinins appear in the serum. A special difficulty in any policy involving the slaughter or segregation of the positive reactors is that many animals in a herd may be infected but still negative to the test; on re-test at some later date non-reactors may then be positive, having in the meantime aborted and spread infection. If infected stock are sold in the open market, infection is disseminated to other herds. Under a new scheme which came into force on June 1 of last year the farmer may pay an annual premium for veterinary supervision, one of the benefits being free inoculation of his cattle with vaccine approved by the Ministry of Agriculture.[4] A. D. McEwen, in a recent review of the main facts about control by vaccination,[5] [6] states that ordinary dead vaccines are useless, and that living vaccines prepared from non-specified strains or from strains which have not been studied experimentally give variable results from time to time, they may infect an undue proportion of the vaccinated animals and should be avoided. He also states that the question of virulence is now receiving official attention, and the attenuated smooth "strain 19" used extensively in the U.S.A. and the rough strain 45 (20) of McEwen are both approved as live vaccines by the Ministry of Agriculture in this country (Standard Vaccines, Nos. 1 and 2). Both these vaccines give a useful degree of immunity, but No. 2 has the advantage that it does not produce agglutinins to confuse subsequent tests of infection. No. 1 vaccine is recommended as a single dose for calves and young non-pregnant cows, revaccination being done at the discretion of the veterinary practitioner, whereas No. 2 is reserved for administration in two doses to older non-pregnant animals. American veterinary surgeons do not usually revaccinate; they hope that a single dose of vaccine to the calf will protect the animal for life. McEwen points out that as No. 2 vaccine does not even cause positive reactions to the agglutination test, there is much to be said in favour of repeated inoculations, about once every twelve months, when the animals are non-pregnant. We question whether official regulations should not stress these "re-call" or "boosting" doses, which have been invaluable in human immunization.

According to Gilbert[7] dead vaccines in an oily excipient have given promising preliminary results in goats and cattle. Felix has suggested that the superiority of such vaccines over ordinary dead vaccines is due to the oil protecting some essential antigen which would be destroyed in the presence of water. The use of dead vaccines obviates one possible disadvantage of live vaccines even of reduced virulence—namely, the risk of infecting the inoculated animal. In view of the variable nature of the disease, field trials with Gilbert's and other types of vaccine should be on a sufficiently wide scale; if successful, the use of a specific vaccine might with advantage be made obligatory on all owners of breeding cattle. It may, however, be asked whether veterinary surgeons, laboratory workers, and stockmen could be safely and efficiently protected with some specially prepared heat-killed vaccine. As regards chemotherapy, sulphanilamide and other compounds have given some promise in the treatment of undulant fever in man, but the results so far obtained in contagious abortion in cattle have been very disappointing.

PHYSIOLOGICAL GASTRECTOMY FOR DUODENAL ULCER

A recent paper by T. H. Somervell[8] describes a new method of dealing with duodenal ulcer. The author introduces us to what he calls physiological gastrectomy, which does away with hyperacidity without the operative risk gastric resection always carries with it and which causes it to be often withheld from the sufferer from duodenal ulcer. It is well known that in a case of old healed duodenal ulcer with a large stomach gastro-enterostomy is eminently successful, but in a case of active ulcer associated with a small hypertonic stomach and hyperchlorhydria this operation may produce new ulcers for old by giving rise to anastomotic or jejunal ulcers, so that the last state of the patient is worse than the first. The object of surgical treatment in this type of case must be to reduce the hyperchlorhydria as well as to divert the gastric contents, and hitherto the only effective way of doing this has been by partial gastrectomy. Somervell produces convincing evidence that ligature of the gastric arteries will so lower the acid concentration as to obviate the undesirable effects hitherto attendant on gastrojejunostomy for the active ulcer with hyperchlorhydria. By a combination, therefore, of anastomosis with ligation—a comparatively simple and safe procedure—the patient may be given complete relief without undergoing the ordeal of gastrectomy, with its risk and liability to subsequent complications such as anaemia. The author of this paper, which comes from a London Mission Hospital in Southern India, states that he has personally performed over 2,000 operations for duodenal ulcer. Economic conditions around the Mission are such that dieting and medical treatment are not practicable, and surgery must be used to render the poor native patient fit to resume his staple diet of curry and rice or curry and tapioca. Perhaps the chief appeal of this paper is the advantage which this innovation in surgical technique would appear to offer over the more mutilating procedures at present in vogue.

A NEW JOURNAL

The *Health Education Journal* (1s. 6d.), which has just been issued, is a quarterly periodical published by the Central Council for Health Education. It replaces the former *Health and Empire* of the British Social Hygiene Council. It is perhaps not quite clear for whom this journal is intended, but it is presumably more for the increasing number of lay workers who now interest themselves in health problems, and for teachers, than for medical men. The doctor will, however, find much to interest him in the current number, and especially will get some idea of the sort of problems that are facing those who are valiantly trying to lead people into hygienic paths. An editorial introduction is followed by a report of an interview between the Editor and the Minister of Health, who says that the function of the new journal is "to act as the guide, counsellor, and friend of all those concerned with promoting the health of the people." Another recorded interview of interest is one with Dr. Allen Daley, Medical Officer of Health to the L.C.C. and one of the pioneers of health education in this country. Dr. Daley makes a valuable point when he says that the results of the different methods of health publicity should be assessed by mass observation methods. Other articles include one by Dr. Charles Hill on the "Radio in Health Education," by Prof. Mackintosh on "What are We Trying to Do in Health Education?", by Dr. Harley Williams on "Making Health Films," by Sir Drummond Shiels on V.D. publicity, and by Dr. L. J. Picton on the function of the general practitioner. The point should perhaps be made that, however effective the various ways of conducting health propaganda may be—radio, film, booklet, leaflet—none of these can compare with the most important medium of all, the general practitioner of medicine. It is he who really has the ear and the confidence of the men and women who seek his advice. One function of health education would therefore seem to be to provide solid information on various aspects of health that would be of interest to the general practitioner, who has little time to collect facts and figures but is the best person to make use of these in persuading those with whom he comes into contact to seek for health.

THE PRE-CLINICAL YEARS

WITH SPECIAL REFERENCE TO THE TEACHING OF PHYSIOLOGY

BY

C. F. J. CROPPER, B.A.Oxon, M.R.C.P.Ed., M.R.C.S.

Major, I.M.S.; lately Professor of Physiology, University of Rangoon

The purpose of this article is to examine the problem of pre-clinical instruction and to plead for a more imaginative treatment of it, and this with special reference to the teaching of physiology. There is no more pressing problem in the whole of medical education than the nature of the instruction in the pre-clinical years. An increasing weight of opinion, expressed in the medical press and in speeches, is stressing the need for bolder and more honest efforts at bridging the gap between the pre-registration science course and the clinical stage—that is, for making the Second M.B., B.S. of greater value to the student. Great strides have been taken in some of the more progressive medical schools, but if the textbooks are any criterion a more sweeping policy is called for. Are those in whose hands the instruction lies rising to the occasion and responding to the increasing demand for truly pre-clinical teaching?

It is a somewhat disquieting experience to compare what one might call the spirit of the "Resolutions of the General Medical Council in regard to Professional Education adopted on May 29, 1936," with the spirit of the average physiological textbook recommended for medical students. If the former be studied (pp. 3 and 4) it will be seen that the emphasis has shifted tremendously towards the clinical in pre-clinical instruction, and that the teacher is given the widest possible scope and freedom of presentation. So marked is the divergence of accepted pre-clinical teaching from this standard that we find the leaders of the profession putting forward a most earnest plea to the teachers of anatomy and physiology to mend their ways. The masterly summing up of Lord Horder (1939) calls for extensive quotation:

> ". . . Of the prospective doctor's pre-clinical work I have said again and again that the motto should surely be *Respice finem*. I think we saw an unfortunate setback when the medical schools decided to put pure anatomists, pure physiologists, and pure chemists at the head of their departments. Each professor has quite naturally wished to stake out his claim and make it as large as possible. The position has been partly redeemed during recent years by a closer association of the heads of the departments with their clinical colleagues in the college committee. . . .
>
> But it is in the teaching of physiology especially that we still see too much cleavage from the later clinical work. The transition from the first to the second of these two parts of the student's work should be much less abrupt than it is. Indeed, it is not at present really a transition at all; it is almost a complete break. After all, what is disease except a state of morbid physiology? . . .
>
> Yet that utter strangeness, that scared and helpless look, in a new-time clinical clerk, which too often remains with him for several weeks or months, what does it mean unless this—that there is in his mind the thought that he is about to embark upon an entirely new voyage for which he is quite unprepared? To change the metaphor, his approach to the patient is as to a strange animal which he has never yet met, and whether the issue will be fraught with a peaceful or bellicose issue he cannot say. It *is* a strange animal that we face him with, physiologically, psychologically, and, even in great measure, anatomically. . . . Until we succeed in bridging this gulf we shall not effect a real improvement in our present system. . . .
>
> With regard to the use of various instruments that are absolutely necessary for the purpose of the routine examination of the various parts of the body, I long ago advocated that the technique of these should be mastered early—that is, in the physiology classroom. I referred to the stethoscope, the laryngoscope, the auriscope, the ophthalmoscope, and the blood-counting apparatus. . . . The larynx is a natural object in health, and the trick of seeing the vocal cords should be learnt as part of the physiological training; once learned it is not likely to be forgotten. It is the same with the retina: this is a normal structure, and how does one see it except with the ophthalmoscope? But when I ask a new clerk to look at an optic disk he excuses himself on the ground that he is unfamiliar with the instrument. But it is quite likely that he knows a great deal about the theories of colour-blindness, or did when the fear of meeting the question at an examination was upon him. . . . And, in the same sense, if time presses, as we know it does, would it not be a good exchange to omit the study of the minute structure of the organ of Corti, and to learn how to see the drum of the ear? A great deal of my time in the wards was taken up in teaching first-time clerks this physiological routine. This should not be the best use that can be made of a physician who is supposed to be experienced in clinical methods and in the arts of diagnosis and treatment. . . .
>
> These examples of the ignorance of the normal at the time of entering the wards and the out-patient departments do not end with lack of acquaintance with simple instruments. The means by which the erect position is maintained and the mechanism of the normal human gait are generally quite unknown subjects. The significance of the knee-jerk and ankle-jerk, and even the method of eliciting them—normal things again—are nearly as foreign to most students at the end of their physiological training as is the use of the instruments to which I have just alluded. . . . This lack of preparedness for clinical instruction causes the student to advance a very little way indeed during his first clerkship. . . . If these and several other *ad hoc* matters in physiology and anatomy are to be included and emphasized during the pre-clinical days, it is clear that some things must be shortened or excluded. The selection of these should be made by a joint committee of all teachers interested, not merely by those who teach the subjects which require curtailment. It should not then be a very difficult matter to come to some satisfactory conclusion. . . ."

No more comprehensive or more progressive pronouncement on what pre-clinical teaching should be has been made, and Lord Horder's main thesis relating to staff and to the content of the teaching cannot be too often reiterated. A few of the salient points from our experience at the Rangoon Medical College under these two headings will be given.

The Question of Staff

In the Rangoon Medical College the chairs of anatomy and physiology are in peacetime filled by Indian Medical Service officers with several years' experience in general medicine and surgery, and surely this should be axiomatic in all such appointments, except perhaps in the provinces of biochemistry and of histology, though even here a strong medical bias is essential. In a number of medical schools such an opinion will be looked upon as sheer heresy. But how, otherwise, is it possible to feed to the pre-clinical student that meat which will prepare him for his clinical activities? The pre-clinical teaching needs to be clinically alive, and this will rest on the teacher's personal clinical knowledge and his ability to inject this in provocative doses into the pre-clinical subjects. He needs to approach his task with sufficient breadth of vision to ensure the retention of essentials and the presentation of the matter from what will be fundamentally a clinical viewpoint.

It would seem that the medical schools should steadfastly set their face against their pre-clinical teaching remaining solely in the hands of the "pure scientists." This applies to organic and physical chemistry as much as to other subjects. The pure scientist in any branch of the subject tends to demand from the student a far too detailed knowledge of that branch.

The Content of the Teaching

Surely we need so to teach the pre-clinical subjects that the student will later look back on his two years with real appreciation of their value to him. Is it rare for the fourth-year student or the senior qualified man to regard his pre-clinical years as rather something which he was glad to be done with and to feel that these two years of hard labour were largely wasted? It is not unknown for the pre-clinical years (which can be made such a dreary drudgery) to be looked back on with a certain bitterness, tinged with a wry amusement. If Lord Horder's motto, *Respice finem*, were truly observed this state of things could never arise.

But the voice of discontent is largely inarticulate: the practitioner soon becomes too concerned with immediate problems to feel the lot of the next generation of students on his conscience, and the student is too bewildered even to realize that he is not being taught on the right lines. Indeed, this article is largely an appeal to the teacher to put himself more often and more sympathetically in the student's place—upon whom the increasing developments of modern medicine already "bind burdens grievous to be borne," without the pre-clinical teacher adding unnecessarily to these burdens. There is something inhuman about a teacher whose notion of preparing a student to deal with such problems as infant feeding or the aetiology of jaundice is to initiate him into the mysteries of chronaxie, the arginase system, or the Hamburger effect. If the net result of the two years' work is the entry into the wards of students flagging in interest and in energy its object is wholly defeated.

There is sure to be an outcry from many quarters at the suggestion that the pre-clinical course is overburdened. It is contended that a drastic pruning of the traditional subject-matter amounts to "spoon-feeding" the student with dogmatic and ready-made examination material; but the fact is, that the student will find abundant stimulus for his reasoning faculties throughout his whole course—that is, to give him an education in the widest sense—and the more abstruse details of anatomy and physiology can soon be mastered by those requiring them for higher studies. The pre-registration subjects alone provide ample opportunity for the inculcation of the scientific method and habit of thought. The principle of pruning, of course, lends itself far more readily to physiology than to anatomy, where it seems at first sight that the subject can be taught only as a whole. But it should not pass the wit of man to devise some way of lightening the task of the student.

There is one point which is often overlooked in the discussion of educational problems, and that is, that the atmosphere and content of the teaching depend not at all upon the curriculum "as advertised" but upon the individual teacher's interpretation of that curriculum. An admirably detailed description of a progressive physiology course has been given by Lee, Boissard, and Hines (1940).

The Case of Physiology

A few salient points from our experience in the Rangoon Medical College in regard to the teaching of pre-clinical physiology will be given. Experience has shown the need for close collaboration between the teachers of anatomy and of physiology, and this for several reasons. It is plainly desirable that any discussion of the function of a system or organ should, where feasible, be preceded by the anatomical study of that system or organ, especially where the nervous system is concerned. Furthermore, overlapping—as, for example, in the case of the tracts of the cord and in the case of the internal ear—can be avoided.

There is nothing original at Rangoon about the general layout of the two years' work. As in most medical schools, the first year's programme includes organic and physical chemistry: perhaps we may look forward to the time when this subject becomes part of the pre-registration curriculum. It is taught in the department of physiology by the lecturer in biochemistry, being merged into the later biochemistry, so forming an integrated whole—"physiological chemistry."

During his first three months in the department the student is naturally a good deal preoccupied with the necessity for passing the examination in organic and physical chemistry; for this reason we do not overburden him at first with physiology; for the first two months he is given a preliminary course covering in the simplest possible terms the whole range of the subject. At the same time he is doing practical work on the blood cells. The succeeding lectures deal with each system in detail: first the blood, then the excitable tissues, reflexes, autonomic system, and the circulation, in that order. This order has been deliberately chosen; it is found convenient to begin with the blood, as it is a section of physiology demanding less knowledge of anatomy and biochemistry than any other. In less degree this applies to the other sections mentioned; at the same time the studies of muscle and nerve, the reflexes, and the autonomic system form necessary preliminaries to that of the circulation. This completes the lecture work of the first year. Meanwhile the practical work has comprised the whole of histology (taught largely with a projector) and a course in "first-year" biochemistry.

The arrangement of the theoretical work of the second year is less of a problem, since the student is now beginning to be able to dovetail one system into another. The central nervous system is studied comparatively late in the second year in order to ensure that all have completed its dissection. Every sixth lecture takes the form of a demonstration on a patient of some aspect of physiology. The selection of suitable types of case for these demonstrations may be regarded as one of the most important of the teacher's duties. The practical work in the second year comprises more advanced biochemistry (largely quantitative estimations, as of the blood sugar) and "experimental physiology." The latter consists of the simpler muscle - nerve experiments, followed by instruction in the handling of the diagnostic instruments; the students are encouraged not to be content until they have mastered the knack of seeing the vocal cords, the fundus, and the tympanum. Where possible, the practical work is arranged to keep pace with the lectures.

There is a very deliberate effort to make the atmosphere of the department a truly pre-clinical one in the full sense of the term. The medically qualified members of the staff are expected to spend a few hours every week in the wards and to keep in touch with the medical journals, to prevent their drifting into a narrow departmental groove. Woven into the texture of the lectures and practical work are clinical procedures, terms, and nomenclature. Illustrations are taken, where possible, from simpler abnormalities of function rather than from solely animal experiments. Of all the hundreds of possible examples, two may be given. In discussing the functions of the cerebellum a far truer picture of their somewhat indefinable nature can be given by noting the results of a chronic lesion of one lateral lobe rather than by dwelling on the effects of extirpation in animals. Then in lecturing on the functions of the duodenum it would seem natural, indeed obvious, to speak in parenthesis of the operation of gastro-enterostomy and the new state of affairs thereby mechanically produced.

It is thus from the outset impressed on the student that disease is itself a "state of morbid physiology." This promise of (clinical) things to come is calculated to introduce the stimulus of genuine interest into the pre-clinical course and to bring it into perspective with the succeeding stages of the medical curriculum. The student will pass on to the Third M.B., B.S. work already accustomed to think in terms of "the patient" and familiar with the clinical outlook and with many typical clinical problems.

MEDICAL AID TO THE WOMEN OF INDIA

The greatest difficulty which the hospitals of India are facing, according to the latest report of the Countess of Dufferin's Fund for supplying medical aid to Indian women, is the shortage of sisters and staff nurses owing to the demands of the Army. When it is considered that there are as yet only 5,000 registered and fully trained nurses in the whole of India as compared with twenty-one times that number in Great Britain. and that many of these have been trained in small, poorly equipped hospitals, it says a great deal for the work that the hospitals have been able to carry on at all, not only caring for the patients but training pupil midwives and nurses. Two new hospitals have recently been opened, the Alice Horsman Memorial Hospital at Cawnpore and the Lady Sandeman Hospital at Quetta. Particulars are given in the report of the 23 hospitals under officers of the Women's Medical Service. The largest of these is the Lady Hardinge Medical College Hospital at New Delhi, with 345 beds, staffed by 10 members of the Women's Medical Service, with 2 others in training, and 21 assistant surgeons. During the year 2,493 operations were carried out at that hospital, and in the obstetrics and gynaecology unit 1,265 midwifery cases were received and 447 obstetrical and 786 gynaecological operations were performed. The next largest hospitals are the Lady Dufferin Victoria Hospital, Calcutta, with 177 beds, and the Lady Lyall Hospital, Agra, with 155. Reference is made to the difficulties resulting from the lack of understanding of modern medical needs by some of the municipal and other members of hospital managing committees. In most of the municipal hospitals very low fees are charged, because it is considered that taxpayers and their families are entitled to free treatment, and thus well-to-do patients take advantage of the facilities offered.

Reports of Societies

PREVENTION OF ACUTE PYOGENIC INFECTIONS OF NOSE AND THROAT

At a meeting of the Section of Laryngology of the Royal Society of Medicine on March 5, Mr. V. E. NEGUS presiding, a discussion took place on the prevention of acute pyogenic infections of the nose and throat.

Methods of Spread

Prof. A. FLEMING said that the nose in health was more or less sterile except for the anterior nares, where there was a quite simple flora as a rule. Staphylococci were found in the anterior nares of 90% of infants in hospital, in 56% of young children, and in from 20 to 40% of adults. An investigation of students and nurses showed 25% of them to have pyogenic staphylococci in the anterior nares, and among out-patients generally a proportion as high as 75% was found. The post-nasal space contained more bacteria and the tonsils had an abundant flora. Certain antibacterial substances occurred in the respiratory tract, notably lysozyme.

Methods of spread of infection were varied, but all depended on the expulsion of the infective agent from the nose or throat into the air or on to clothing, etc., from which it might pass to someone else. It was always found in infectious diseases wards that after beds were made, especially if they were made violently, there were far more organisms in the air than before. It had been stated that 70% of scarlet fever patients became infected in hospital with a streptococcus other than the one they took in. If the instructions in M.R.C. Memorandum No. 6 on the dressing of wounds were obeyed there would be less cross-infection. Many masks worn were quite ineffective. The American system of sterilizing the air with ultra-violet light seemed in some circumstances to work extremely well, but in others not so well. Persons liable to infection could be immunized up to a point, but it was not practicable to increase the resistance of everyone who might be exposed to risk. Resistance could be increased by watching for and dealing with any abnormality that increased the likelihood of infection. A sulphathiazole snuff was offered as a means of getting rid of staphylococcal and streptococcal organisms in the nose, and in some cases it seemed to do what was claimed for it. Sulphapyridine had been made into a chewing-gum, and it was found that after two hours' chewing there was an appreciable amount in the saliva, so that a wash of sulphapyridine was obtained over the tonsils for a long period. An important principle in prevention was the education of the nurse in bacteriology.

Clinical Aspects

Mr. E. D. D. DAVIS said that isolation was often impracticable and too expensive in personal restrictions to receive general adoption, but more could be done to prevent infection than was usually the case. Greater efforts could be made to prevent streptococcal infections in schools. Isolation in schools and institutions was practicable, and the wearing of masks for the nose and mouth in and out of the sick room should be encouraged. The study of aerobiology was an important adjunct to public health, and included the ventilation and air-conditioning of public rooms and the purification of air by ultra-violet light, and by chemical means such as a harmless spray of propylene glycol.

It was stated that streptococcal infections of the nose and throat had an incubation period of from two to four days, but for how long a streptococcal patient was infectious was not known. It was suggested that he was a source of infection during the period of fever. The immunity produced by anti-catarrhal vaccines was said to be from 7 to 12 months. On the question of the carrier, haemolytic streptococci could be found in the pharynx or nasopharynx for as long as six weeks after a cold, equally in patients who had had their tonsils enucleated and in those who had not. The throats of 100 normal students were investigated bacteriologically every month, and an average of 15 to 20% were found to be carriers of haemolytic streptococci. Enucleation of the tonsils simply because the patient was a carrier was useless. If the carrier was sent away for a fortnight the streptococci usually disappeared, but this meant a serious depletion of nursing and medical staff. Gargles, antiseptic swabbing, sprays, and lotions had little effect, and so the wearing of a mask was enforced. A spray of 5% sulphathiazole was being tried.

As for the prevention of infection before, during, and after operations, tonsil and adenoid operations for children should be avoided during so-called influenza epidemics, which were common in January and February. If the temperature of the patient was above 99° F. on the evening or morning a deliberate operation should be postponed. A clean mouth was a necessity. Carious and loose teeth should have received attention. The use of a tooth brush and mouth wash immediately before operation was often overlooked. At operation unreasonable trauma of nose and throat by curetting and tearing was to be avoided.

In considering the post-operative state the construction of the hospital ward was important. Ear-nose-and-throat wards should not contain more than 12 beds, supplemented by single rooms for isolation of cases. The wards should be divided into groups of 4 or 2 beds by fixed glass screens reaching to a few feet short of the ceiling, and the beds should not be less than 6 ft. apart. An adequate number of small side-wards for septic cases was essential, and a solarium or recreation room with access to a balcony was most desirable. The operation case was much better without lotions, sprays, and gargles, and the operation wound should be left alone.

Discussion

Mr. V. E NEGUS said that at Horton Hospital an interceptor mask of very simple construction—merely a piece of *x*-ray film on a wire frame—had been introduced and had proved very effective. At all events it prevented organisms from being directed straight into the pharynx or nose of the receiver. It was possible for a so-called carrier to be a carrier only at certain times—as, for example, immediately after being in contact with a patient who had some streptococcal infection. Mr. W. M. MOLLISON spoke of the uselessness of the usual gargle. The only method by which the tonsil could be reached seemed to be the sucking of lozenges or the use of chewing-gum.

Mr. T. B. LAYTON said that beds should be at least 10 ft. apart, and in the construction of any new ear-nose-and-throat ward he would demand 12 or 15 ft. On the question of isolation, he said that this method was the limitation of the freedom of the individual for the benefit of the community, but unless there was no doubt at all that it was for the benefit of the community the individual should not have his freedom limited. In convalescence isolation was harmful for the patient. He did not think that any child should be submitted to solitary confinement under the name of isolation for a longer period than three weeks. There was no doubt that mental influences lowered the powers of resistance of the individual to infective organisms, and one of these influences was the unhappiness which attended isolation. Mr. R. G. MACBETH described the construction of a hospital in which abundant provision had been made for bed spacing and for glass screens, and said that the result had been greatly to diminish, even to insignificance, the percentage of cross-infection. An experiment with air-conditioning had shown that after the air was conditioned the number of colonies of micro-organisms had diminished to one-tenth.

Mr. LIONEL COLLEDGE said that he had had several midwifery students sent to him who had been prevented from carrying out their midwifery course because they were carriers—not, apparently, transitory carriers in the manner described by Mr. Davis, but having a carrier period lasting for at least three months. The only thing to be done was to remove the tonsils, and, so far as he knew, it had succeeded, but it was a serious thing to subject anybody to an operation, however trivial, for other than a medical reason. Mr. EWART MARTIN said that the nasal mucus was a most important part of the barrier system against air-borne infection and could be destroyed by the use of antiseptics and also by the use of oils Dr. D. J. GUTHRIE suggested that the use of animal mucus—mucin—as an antiseptic might be tried. Prof. FLEMING, replying to this last point, said that if it was required to infect animals with the staphylococcus for experimental purposes the thing to do was to put the organism in mucin. These organisms did not infect in small doses without mucin. The mucin offered for use in medicine was not, of course, the substance as it came from the animal; it had been treated in various ways, quite enough to destroy any ferment, before it became the commercial mucin. A good deal of work had been done on the lysozyme content of animal mucin, which had been published in the *Journal of Experimental Pathology*.

Free Choice of Doctor

SIR,—As a practising doctor of nearly fifty years' experience, to whom future medical arrangements will make very little personal difference, I should like to support Dr. Lindsey Batten's, Dr. MacWilliam's, and your own attitude to this problem of the personal relation between the doctor and his patient in contrast with the very undemocratic view that some representative body is more competent to choose his personal adviser than is the individual himself. Indeed, this alternative to the democratic method of individual personal choice has a nasty taste of present-day Germany. As Dr. MacWilliam put it: "We want, before every other professional consideration, freedom to function as doctors in response to the demands of our patients, and to the satisfaction of the persons immediately concerned." In your leading article of February 13 you say that a complete medical service, including consultant and other services, should be made available for nine-tenths of the population; and you say further that the Beveridge proposal is that such a service should be available to the whole population, rich and poor alike. You add: "Whether the compulsory insurance scheme should cover 100% of the population, or only, say, 85 to 90%, is a matter which Parliament has not yet decided or even discussed. Whatever the people of this country, through their representatives in Parliament, may decide on this issue of coverage, it would be undemocratic, not to say foolish, for the medical profession to run counter to the rest of the community. . . . But the doctors of this country do not believe that it is in the public interest that the medical profession should be turned into a whole-time salaried civil service, with the doctor the servant of the State. The doctor must be the servant of his patient."

The panel method of preserving the maximum right of the individual in matters other than the economic one was, and is, a most interesting experiment, but it has never had a fair chance and has had to bear on its shoulders all the faults and limitations of the compulsory health insurance Acts and regulations. It is no fault of the panel system that the working man's family is left unprovided with any medical service; or that the working man himself should have no statutory right to specialist treatment of any kind, or to institutional provision, however urgently necessary these may be. As Dr. Batten—whose claim to a hearing has been well demonstrated by his previous expressions of that rare quality, common sense—puts it: "Our private patients are not always good judges of doctors or doctoring, but this can be said for them: in general they demand from us the best we can give. . . . So far the State, as an employer of practitioners, does none of these things, and it shows no sign of repentance or intention to reform. Its only standard of excellence is that which produces no complaints."

Here are a few quotations from non-medical critics with widely different critical standpoints. The first is by Barbusse, who wrote: "The human reality is the individual . . . and every collective organization of men must come back to the individual man, be quickened by the individual life, and respect individual autonomy to the fullest possible extent." And here is Mr. Cole: "A human being, as an individual, is fundamentally incapable of being represented. He can be represented only in relation to some particular purpose or group of purposes." It has always seemed to me that the importance, even the sacredness, of the individual, and equally of his rights, duties, and responsibilities, is the very essence of the Christian-social ethic and of real democracy.—I am, etc.,

London, E HARRY ROBERTS.

Rehabilitation for Skin Cases

SIR,—In your interesting leading article (March 13, p. 322) you emphasize that rehabilitation must now be regarded as reaching far beyond the province of physical medicine and as including "occupational therapy, vocational training, and the arousal and maintenance of mental interests." This prompts me to draw attention to a field of rehabilitation which is seldom considered—namely, the rehabilitation of dermatological cases.

Those who are not in close contact with dermatological work often fail to realize the degree of depression to which many skin cases are prone; not only is depression engendered in the patients' minds by the fact that they are diseased, but the nature of their disorder (which may make them repulsive to themselves and shunned by their friends) may cause much psychological injury; to this is added the anxiety that, because of chronicity or the tendency of the eruption to relapse, they may not be able to continue to earn their living by the work in which they are trained. Because of these and other anxieties many patients endeavour to supplement the treatment ordered by their doctors by such homely remedies as the frequent use of antiseptic soap or sun-bathing, which, although employed with the best of intentions in order to "harden" the skin, frequently cause havoc and still further increase the period of disability.

If the sphere is to be enlarged so that by rehabilitation is meant a period of retreat from which the patient returns to the world not only improved mentally and physically but also armed with information culled from systematic teaching at the rehabilitation centre as to how he may best avoid the hazards of his occupation and his environment, then rehabilitation should have a wide application in dermatology. Regarded merely from the economic standpoint it may be found to be a paying proposition for certain types of infective and sensitization dermatoses; regarded from the ethical standpoint it will be of inestimable benefit to many.

It may be of interest to note that as a result of the facilities granted by the Ministry of Health and the War Organization of the British Red Cross Society and Order of St. John, a rehabilitation centre for military skin cases will soon be opened. It is hoped that by suitable rehabilitation the invaliding rate of certain types of cases from the Army will be reduced, that in cases in which mental depression is retarding progress the atmosphere and environment of the centre will rapidly cause improvement; and, finally, that from a study of the problems which will arise in this branch of rehabilitation much useful information will be obtained.—I am, etc.,

R. M. B. MACKENNA,
Lieut.-Colonel, R.A.M.C.

Scientific Freedom and Social Medicine

SIR,—Some of the statements in Dr. Geoffrey Bourne's article (Feb. 20, p. 227) are clearly fallacious, but some contain that modicum of truth that makes generalizations from them particularly dangerous. Dr. Bourne writes: "There are in existence at the present time two types of medical service—the autocratic as typified by the L.C.C. and E.M.S., and the democratic as typified by the voluntary hospitals." The decision as to whether a service is democratic or not must obviously depend upon what we mean by democracy. If we regard a hospital as an institution run exclusively for the benefit of the doctors or its staff, then clearly to be democratic these same doctors must have complete control. If, on the other hand, we think that the primary duty of a hospital is the care of the patients in it, then, I submit, to be democratic the final decision on all matters must rest, not with a small percentage of the workers in that hospital—that is, with its medical staff—but rather with the representatives of its potential patients—that is, with the public.

It goes without saying, I hope, that nothing must be allowed to abrogate the duty of each individual doctor to do his best for each individual patient under his care. Moreover, I think that at every hospital there should be a committee of the medical staff through which individual and collective viewpoints can be expressed and transmitted to the governing authority. Nevertheless, there must be some relativity, and no one is likely to blame a hospital board if more notice is taken of the advice of Dr. Bourne than of his junior house-physician, assuming that Dr. Bourne's house-physician has access to the committee. Similarly on matters of general hospital administration, the opinion of the medical superintendent of a municipal hospital is likely to be of greater value than that of a junior officer of less experience.

Of course, the work of junior medical officers in municipal hospitals is under a degree of supervision and even control by senior officers, but it is to be hoped that the same is true of house officers, clinical assistants, etc., in voluntary hospitals. If it is urged that this must be so because of the educational functions of voluntary hospitals, then the same case can be made in respect of junior positions in municipal hospitals, for these positions are very largely held by men and women who come to learn by experience with a view to preparing themselves for more responsible work elsewhere. Much has been said of late of the tyranny of medical superintendents, but it would be helpful if critics would produce concrete examples which can be investigated of alleged interference with the professional work of senior and experienced officers, instead of the vague and general statements which so far have been forthcoming. I submit that the holders of senior clinical positions in the municipal service have full freedom in the treatment of their patients and are given every encouragement to publish scientific papers.

Dr. Bourne would have us believe that the committee of management of a voluntary hospital is willing, almost without exception, to accept the advice of its medical staff. But is this really so? I am old enough to remember acute differences of opinion over the appointment of members of the honorary staff, over the opening or closing of departments, and other matters. I can even recall the board of management of a large voluntary hospital insisting on the resignation of its senior surgeon, in spite of the protests of its medical committee. And the unfortunate thing is that, thinking back, I have little doubt that in almost every case the representatives of the subscribers—i.e., the lay committees—were in the right. I am quite ready to admit that the L.C.C. hospitals are far from perfect. They have a long way to go and much to learn, even from the voluntary hospitals. It must be remembered, however, that it is but twelve short years (and three of them war years) since these same hospitals arose from the "slough of despond" of the Poor Law. Some improvements have taken place, as, I think, all will admit. I wonder if Dr. Bourne can honestly say that more progress has been made in the voluntary hospitals of London in the same period.
—I am, etc.,

Northwood, Middlesex. SOMERVILLE HASTINGS.

SIR,—Having been delighted by Dr. Geoffrey Bourne's statement that "the democratic system of medical service is entirely compatible with State control," I was acutely disappointed to find that the bulk of his article was little more than the enumeration of the faults of the municipal system. I was on the point of compiling a similar list of drawbacks of the voluntary system when I realized that neither set of faults was inherent in its particular system, for I have seen the democratic system working well in a municipal teaching hospital, and I have seen autocracy flourish in the voluntary. Defeatism, in fact, had won the day until I read Dr. F. M. Purcell's disastrous suggestion (March 6, p. 300) that 100,000 copies of Dr. Bourne's article should be distributed free! One further quotation from Dr. Bourne's article is sufficient to show how disastrous is this suggestion: "The public must be warned that an autocratic system will impede the speed and efficiency of medical services." This is, of course, nonsense. The speed of some of our largest voluntary hospitals with waiting lists of from two to five years is precisely one of the factors that will make the country reform us if we do not reform ourselves.

With the fervent hope that Dr. Bourne will develop the thesis first quoted, I commend to his notice an article in the *Spectator* (Jan. 29) entitled, "The New Conservatism." The author states that he "is not impressed by the fear of schemes for social security as destructive of enterprise." The Archbishop of York also has recently described as "contemptible" the argument that social security would destroy initiative and take away incentive to work. I myself know several so-called "slaves" in municipal hospitals who are first-rate "chiefs" doing excellent clinical, operative, and research work, in spite of the soul-destroying drawback of having no private practice to keep them stretched.—I am, etc.,

Edinburgh. A. F. ANDERSON.

Future of Women in Medicine

SIR,—I have read with amusement Dr. Jane Scott Calder's dissertation (March 13, p. 329) on sex in medicine, thinly disguised as a serious attempt to treat of the future of women in medicine. Let us examine her concrete suggestions.

1. That medical co-education is fundamentally dangerous on grounds of (*a*) impairment of work due to proximity of the sexes; (*b*) lowering of standards of modesty and morality Does she really believe that every medical student—man or woman—is concerned solely with sex? Was that her own experience or was she, perhaps, trained at a women's medical school and so has no first-hand knowledge of a co-educational one? Why is co-education specially dangerous in a medical school? Because there are bodies about? What is it that lowers the standards of modesty and morality—lumps of bare flesh?

2. That the entrance age be raised to 22 years on the grounds that all but the best will be eliminated. If the well-to-do are the best this proposition is correct.

3. That a condition of entrance be three years' training as a nurse The effect of this will be to add time to an already long course and to assist in closing the profession to those with straitened means If Dr. Calder's proposal has any validity it must be equally applied to men, who will presumably do a three-years course as male nurses

4. That the aim of the teaching staff be to train medical women, not to teach women to try to be medical men. The aim of medical education is to produce competent doctors.

5. That women should administer to women and children only. It frequently does happen that women doctors deal mainly with women and child patients. This is natural and proper, but it is inconceivable that it should be an irrefragable rule. The training period, in particular, is the time when a woman has the opportunity to become familiar with the mentality of the male patient, so gaining a balanced view of her profession. Would Dr. Calder object to a woman anaesthetist having men patients, or would she prefer her to be hampered by differences in management and technique should she suddenly, as is extremely probable, be confronted with one in an emergency? Would Dr. Calder's purdah also debar a woman pathologist from examining specimens from a male patient?

6. That the hospitals be staffed entirely by women. Is this, on analogy with suggestion 1, to make it quite impossible for sex to rear its ugly head? It is difficult to conceive of any valid reason for depriving students of the best teaching available. Perhaps Dr. Calder is of opinion that a woman-staffed hospital would provide this. If so she is in a decided minority.

7. That the house staff be chosen 75% by special house staff examination and 25% by character and qualities useful to the hospital's future. The path of the medical student and newly qualified doctor is only too heavily beset with examinations, which in any case are a poor test of practical capacity. In selecting officers for house appointments they are unnecessary. The applicants are personally known to the medical staff and can be chosen for character and ability rather than mere book knowledge.

8. That special attention be given to developing a sense of social and public responsibility. This is a quality that comes from within; it cannot be inculcated by "experts," however "sensible."

9. That there should be no birth control clinic at the hospitals From the prominence given by Dr. Calder to this subject I judge it to be a particularly ferocious bee from the swarm in her bonnet. It is obvious that she is in entire ignorance of the principle of birth control, which, briefly, is to space out families.
—I am, etc.,

London, N.W 3 HELEN BOWER ALCOCK.

SIR,—While agreeing with some of the statements made by Dr. Jane Scott Calder (March 13, p. 329) in her thoughtful letter on medical women, now and in the future, she makes other statements which are sufficiently provocative to challenge further discussion.

1. Women are not to demand the same training, opportunities, and privileges as men, for "women are created women: men are created men." Is there, then, a female brain and a male brain? Does the woman doctor approach the diagnosis, prognosis, and treatment of her patients with a different type of grey matter from that of a man? Her psychology is different, but surely her intellect is not.

2. The sexes violate each other's dignity when each invades the other's sphere. Does this imply that a single woman, a widow, or a grass widow must either starve or sell herself in order to live, rather than earn an honest living by taking up a "man's" trade or profession? Is not all labour, whether of mind or body, a worthy and dignified thing if performed with the right motives and carried on with honour?

3. Women are created for the dignity, nobility, and responsibility of wifehood and motherhood. That, surely, is a fundamental fact acknowledged by all, and it would be well indeed if such privileges were the lot of all women. But is there anything undignified, ignoble, and irresponsible in the woman doctor who carries another woman through the travail of childbirth and tends her with skill and loving care? Is the task of the medical woman less truly feminine than the similar task of her professional colleague, the midwife?

4. Co-education is fundamentally dangerous. This is stated to be due to proximity of the sexes, resulting in lessening of concentration and lowering of moral standards of behaviour. If this be so in most cases (there will always be the abnormal person), then early

home training must be sadly at fault, and sex must have obtained an undue prominence in the minds of those concerned. The segregation of women to their own medical schools and hospitals merely accentuates the sex aspect in medical matters, and suggests, furthermore, that the art of medicine deals with something essentially indelicate, if not worse.

5. Let the entrance age for students be raised to 22 years. This will eliminate all, probably, but the best. It would eliminate all but the wealthy. Does Dr. Scott Calder really believe that strength of character, brilliance of mind, and discipline of the emotions are more readily found among the financially favoured than among those obliged to earn their living?

6. Finally, Dr. Scott Calder urges that men and women doctors should work together for the common good. One wonders how this desirable end is to be attained if they are to be segregated from each other in their years of training at university and hospital. The masculine woman is indeed a sorry sight, but feminine attributes are not best perpetuated and strengthened if women are kept apart from their complementary fellow-workers of the male sex.

—I am, etc.,

Knott End, Lancs. MARY CARDWELL, M.D.

SIR,—I read with dismay Dr. Jane Scott Calder's letter (March 13, p. 329) on the future of women in medicine, advocating the separation of women from men during training and in their eventual work—dismay not so much at the future of women as at the future of medicine as administered by a band of women whose tolerance, humour, and insight into character have been stultified by segregation during their most impressionable years.

I deplore this emphasis on sex, which leads not to co-operation with men but to rivalry. We are all servants of medicine, searchers after truth, and on this field there is no need for a woman—to quote Dr. Calder's words—"remembering and being proud of her sex." She should be unconscious of it. When, very occasionally, a new patient murmurs an apology for a necessary display which he imagines may be distasteful to a feminine eye, I reply, "That's all right; while I am here I am not a woman, but a doctor."—I am, etc.,

Birmingham DOROTHY ROUGHTON.

Vitamins and Physical Efficiency

SIR,—It is clear from the opening sentence of their article on this subject (Feb. 27, p. 243) that Drs. A. A. Harper, I. F. S. Mackay, H. S. Raper, and G. L. Camm assume that the average student's diet is deficient in vitamins, and that such deficiency has been responsible for deterioration in fitness, since they were able to detect an improvement in resistance to infection and other minor deviations from health as well as in physical efficiency when vitamin supplements were administered to their experimental subjects, cadets at Manchester University. I am not quite sure that these are fair assumptions; but, accepting them as such, my interest is particularly directed to their consideration of "fitness" from two entirely different aspects. I recall a recent report of a similar investigation performed upon a number of school children in whom no advantage whatever in respect of general health and freedom from sickness appeared to accrue from the administration of vitamins. I am not in a position to cite the original report, but Dr. Harper and his colleagues are satisfied with a difference in favour of experimental subjects over the controls which is statistically significant, and anyway it is not my intention to deal with this side of their investigation.

But the authors are also satisfied that there is a corresponding gain upon the physical side, a gain in physical fitness on the lines one is accustomed to recognize in regard to athletic capacity. This improvement they accept as a reflection of the lessened susceptibility to minor infection, or as due to some other action of the vitamins. Now this, surely, is opposed to general experience. The highly trained athlete is by no means immune to infections; on the contrary, he is often particularly susceptible. On the other hand, a high degree of resistance to a bacteria-saturated atmosphere is only too often accompanied by a wretchedly low level of fitness, using that term in the accepted athletic sense.

The possible relation of vitamins to training and to the highest possible level of athletic capacity has naturally appealed to those of us who have been interested in athleticism and allied subjects during the past couple of decades. Ever since men have undertaken feats of speed or endurance, the dietetic side of training has always occupied a prominent place, and claims for superiority have been credited to every article of foodstuff and every kind of system: the more bizarre the greater the appeal to the imagination. Yet a critical consideration has led to the conclusion that there may be equally good results with widely different dietaries. I am speaking, of course, of pre-war days, when there was unrestricted access to any and every kind of foodstuff, so that individual peculiarities and tastes were untrammelled.

Yet there was a certain wish to believe that there might after all be something in the idea that this, that, or the other vitamin had some special relation to athletic capacity. The craving which men in full training experienced for some prohibited or greatly restricted article of diet might then indicate a natural necessity rather than the original sin which old-time trainers discouraged or reprobated. I myself have been at times impressed by the craving for butter; but here it was naturally difficult to distinguish the high-calorie value itself from the fat-soluble vitamins as the essential factor. At one time vitamin B made a bold bid for popularity, and I recall the amusing pronouncement of one authority, with a journalistic flair for the sensational, advocating its liberal administration to athletes, who are notoriously "highly strung," to ensure an adequate provision of the antineurotic vitamin!

I should feel more drawn towards the conclusions in this article and prepared to disregard the usually accepted antagonism between resistance to infection and athletic fitness, and to recommend the administration of vitamins to would-be champions, if I were satisfied with the nature and the records of the tests employed. These included the breath-holding time and the endurance test, familiarly known as the "40 mm. test." I have never been able to accept these as standards of physical fitness, not because they do not indicate some special capacity but because practically all athletes whom I have tested, especially by the latter method, fail miserably in their performances. I do not recall a single example of a man exceeding 50 seconds in the "40 mm. test." I have examples of men of the most supreme physical fitness—athletic champions with world's records to their credit, long-distance cyclists capable of exceeding 20 m.p.h. continuously for twelve hours—who faded out at 20 to 25 seconds. Yet these cadets under consideration averaged practically a minute at their first examination. One of two conclusions seems unavoidable: either that a number of supermen must have been included, which is surely inadmissible, or that the criteria of the performance and interpretation of these tests were very different from those we are accustomed to recognize.

The authors were puzzled by the anomaly that notwithstanding the administration of the vitamins the resting pulse rate became faster and not, as they had expected as a concomitant of improved physical fitness, slower. Their controls showed a diminution of 7.5 beats per minute; those who received vitamins a diminution of approximately 5 beats per minute. So slight a difference appeals to them as significant. As the result of many thousands of observations over 30 years I am prepared to accept a variation of 10 beats per minute as within normal limits, especially in regard to young men of this age whose autonomic nervous system is relatively labile. I am inclined to regard the post-exercise deceleration test as of value in assessing physical fitness, an investigation which I note was undertaken by Dr. Harper and his colleagues, who found, as I would have expected, no significant difference as the result of vitamin administration.—I am, etc.,

London, W.1. ADOLPHE ABRAHAMS.

Abortus Fever

SIR,—I was very glad to see Dr. D. G. Leys's article on abortus fever (Feb. 13, p. 187), in which he reports eight Scottish cases of this disease, illustrating the extraordinary variety of its manifestations and the consequent ease with which the correct diagnosis may be missed. There are many points in his descriptions and comments which are of great interest and which I would gladly discuss, but knowing the restrictions from which you suffer I will confine myself to a few observations which Dr. Leys and others may perhaps find helpful.

Dr. Leys remarks that "the disease does not appear to be a cause of abortion in women, for more than one case has been observed in an undisturbed pregnancy." It is quite true that the great majority of pregnant women suffering from this disease do not abort and that the reality of such an occurrence was long in doubt. There are now, however, a number of well-authenticated cases. The most convincing of these is perhaps the one recorded by Carpenter and Boak[1] in which *Br. abortus* was grown from the vaginal contents in a case of incomplete abortion, and was also recovered by guinea-pig inoculations of an extract of the entire foetus and placenta. This organism was identified culturally, morphologically, and by the agglutination and complement-fixation tests as a bovine abortus strain. An equally convincing case, but in this instance due to infection with *Br. melitensis*, was reported by Janbon and de Kerleau[2] in a tripe worker at a slaughter-house. This woman had had nine pregnancies, of which eight resulted in normal labour but one ended in spontaneous abortion, and the causative organism was isolated from her blood, her uterine discharge the day after delivery, and from the spleen, liver, heart's blood, and gastric contents of the foetus as well as from the placenta and placental exudate.

An interesting group of cases was reported by Simpson and Frazier[3] in which five women who had suffered from repeated abortions, and in whom a Wassermann reaction was negative, gave a positive agglutination against abortus to a titre varying from 1 in 80 to 1 in 320. All these women drank raw milk, and in four of the cases there was a history of fever. Frei[4] has reported the case of a woman who had a normal pregnancy in 1922 but later had four successive abortions. Her husband was a farmer whose cattle became infected with *Br. abortus* at the end of 1922. In May, 1928, subsequent to the four abortions, *Br. abortus* was found in large numbers in the woman's cervical discharge, and in July of the same year her blood was found to agglutinate the organism to a titre of 1 in 400. As regards my own series of 616 cases, abortion was reported in only one case. The evidence in this case was incomplete, but the clinical history and an agglutination titre of 1 in 1,000 leave no doubt that this was a case of undulant fever. The patient aborted about the seventh month, but apparently no attempt was made to grow the organism from the placenta, foetus, or vaginal discharge.

In speaking of the diagnosis of this disease Dr. Leys says that the "agglutination test seems to provide all that is required for a positive diagnosis." While agreeing that this test is far the most valuable diagnostic agent we have, one should not lose sight of the fact that cases do occasionally occur in which agglutinins are absent but the diagnosis is beyond doubt. One of the pioneer workers on this disease suffered for a number of years from a complaint which she firmly believed was undulant fever, but a number of distinguished doctors who investigated her case refused to accept this diagnosis until the organism was eventually grown from her blood. During all this time repeated efforts to detect specific agglutinins in her blood were uniformly unsuccessful. This, of course, furnishes an additional reason for attempting a blood culture with the special precautions (such as growing in 10% CO_2 and preserving the culture for three weeks instead of three days) which are called for in the case of this organism.

Dr. Leys is right in supposing that meningism is uncommon in this disease, but it is not by any means unknown. Three cases have occurred in my series. In one, stiffness of the neck was the only sign, but in another neck rigidity was accompanied by a positive Kernig's sign, tremor of the hand, pin-point pupils, slurring of speech, and intense drowsiness, and on spinal puncture the fluid showed slightly increased pressure, though it was clear and the cell count was normal. In the remaining case the neck stiffness was accompanied by the absence of both ankle-jerks and one knee-jerk, and on lumbar puncture the blood was normal apart from a colloidal gold reaction of 1223321000. He will find some interesting accounts of similar cases in papers by Molinelli, Miyara, and Basso;[5] Olin,[6] Hardy, Jordan, and Borts,[7] and Sfez and Cohen-Boulakio.[8]

Lastly, with regard to treatment, I agree with Dr. Leys that nothing like a specific remedy has been found for this disease, and that on the whole the results obtained with the sulphonamide compounds are disappointing. He will find the details of the results in my series in a letter of mine which you published in 1941.[9] By far the most successful remedy in my experience is protein shock with T.A.B. vaccine. Of thirty-four cases in my series which were so treated, definite benefit was obtained in twenty-five, doubtful benefit in five, and no benefit in four.—I am, etc.,

Ministry of Health, S.W.1. W. DALRYMPLE-CHAMPNEYS.

Weil's Disease

SIR,—Writing of Weil's disease Dr. K. Blum (Feb. 20, p. 231) advises that every illness with jaundice and high fever should be suspect. It should be emphasized, however, that if jaundice be considered a necessary diagnostic feature many examples of the infection will be overlooked, as more than 50% of cases of Weil's disease do not develop jaundice. In fact, jaundice is no more necessary for the diagnosis of the disease than is a rash for the diagnosis of typhoid. From classical attacks with jaundice to inapparent infections recognized only in retrospect by serological tests, a wide range of clinical types—for example, those presenting influenzal, meningeal, respiratory, or abdominal features—may be encountered. Weil's disease is always worth considering when faced with a clinical picture in which fever, generalized muscular pains and tenderness, conjunctival and scleral vascular injection, and a polymorphonuclear leucocytosis for which there is no obvious cause are predominant. The suspicion should be strengthened if the urine contains albumin, cells, and casts, and if there has been the risk of contact with material contaminated by rats. Cases are particularly to be found among those whose occupations bring them into contact with such contaminated material. During the war of 1914–18 there were many among soldiers from rat-infested trenches, and although these conditions have not been reproduced in the present war, cases may occur in soldiers infected through the inevitable minor abrasions associated with field training or through immersion in water where rats may be present. Military medical officers should therefore be on the look-out for the disease.

Diagnosis is most conveniently confirmed by the agglutination reactions of the patient's serum, the titres rising to significant levels between the first and second weeks of the illness. Adhesion and lysis tests are less commonly employed, and recovery of the organism from the blood during the earlier stages and from the urine during the later stages of the disease makes considerable demands on technique and time. In this connexion it may be remarked that the organisms soon die in acid urines, and, therefore, delay in dealing with such specimens rapidly diminishes the chances of successful isolation; it has been suggested that alkalis should be given to the patient in order to render the urine alkaline when recovery of the organism from the urine is desired. Bearing on this matter is the observation that epidemics of the disease among the cane-cutters in Queensland tend to occur after the heavy rains, which reduce the acidity of the soil and so assist the survival of the organism. In the treatment the early administration of anti-leptospiral serum should be considered, as it is difficult to forecast accurately the course of a case of Weil's disease.

Whatever may be meant by the reference to the relationship between "ordinary infectious hepatitis in wartime" and "morbus Weil," white blood cell counts are a valuable clinical means of differentiating leptospirosis from the common infective hepatitis which is now so widespread. A leucopenia with relative lymphocytosis is commonly accepted as characteristic of the latter infection, although perhaps the exact deviations of its blood picture may still be open to some question. On the other hand, there is no doubt about the valuable diagnostic association of a polymorphonuclear leucocytosis with Weil's disease.—I am, etc.,

London. F. MURGATROYD.

Anaesthesia for Laryngofissure

SIR,—I entirely agree with Mr. L. Colledge (Feb. 20, p. 230) and Mr. W. Howarth (March 13, p. 334) with regard to the use of morphine in laryngofissure and, indeed, either before or after any operation of a severe nature on the upper air or food passages; it should never be administered. I agree with Mr. Colledge, but I disagree with Mr. Howarth, about the temporary tracheotomy in laryngofissure. One great advantage is that if a disk is removed from the anterior wall of the trachea plugging can be inserted from below before opening the larynx; this entirely prevents the passage downwards of blood into the trachea and bronchi.

I well remember two cases which prove the advantage of preliminary tracheotomy. On one occasion in a nursing home of a large provincial town I operated on a man of 16 st. who had a high blood pressure. I succeeded with some difficulty, owing to excessive haemorrhage, in removing the growth, but nothing short of very firm packing would stop the somewhat alarming bleeding from the cavity of the larynx. The packing remained in position for about 3 hours; and when it was removed there were no signs of haemorrhage, and I returned to London feeling that if there was any more haemorrhage it could easily be controlled, as the tracheotomy tube, needless to say, was left in position. Fortunately there was no further trouble.

Another patient developed alarming haemorrhage 48 hours after operation, and I reached the nursing home just in time to save his life; owing to the presence of a tracheotomy opening I was able to arrest the bleeding. Had the operation been performed without tracheotomy there is little doubt the patient would have died, probably before my arrival. As a matter of fact he survived for 7 years and eventually died of cerebral haemorrhage.

Even supposing the absence of an opening in the trachea resulted in an increased mortality of 1%—and I am convinced this is too low a figure—it would be worth while to carry out tracheotomy in every case, as it is a perfectly safe procedure.—I am, etc.,

Aylesbury. NORMAN PATTERSON.

War Neuroses: Their Nature and Significance

SIR,—It is interesting that Dr. W. Ronald D. Fairbairn (Feb. 13, p. 183) has brought out the important problem of morale as the result of working from the E.M.S. angle. This focus has emerged from a mass of clinical findings observed from bringing peacetime psychotherapy to bear on wartime neuroses in the combatant Services.

The psychiatric services have a foot in each of the combatant and the civil-social camps, and they are trustees for both. They have thus a difficult task, and have had to create their own framework and evolve within this, and more and more has it become apparent that accurate psychometric assessment is the major issue for shaping a policy and avoiding the necessity for treatment of breakdowns, which is likely to be more than usually difficult and disappointing. Most psychotherapists will not quarrel with Dr. Fairbairn's psychopathology in regard to psychogenic anxiety, but one is not so clear about some of his inferences. Morale is a factor that is going to concern peacetime social life after fighting ceases, and one aim of psychotherapists in the Services must be to diagnose functionally unfit men and return them into civil life before there has been an undue loading of their psychological defences, for these are what they need in civil life.

What does the psychotherapist mean by "morale" when he is discussing this with his colleagues? When a man who has not previously shown delinquent traits begins to lose his morale in the Services and to cease to pay attention to authority and what his fellows think of his behaviour, is he suffering from a regression (in the psychological significance of the term) or is he tending to revert to something nearer akin to his animal ancestry (in the atavistic and biological meaning of the word)? Spinoza once remarked that "the stone in the air would think itself free if it could forget the hand that had thrown it." If man could forget man's hand he would begin to feel he had lost contact with his social sense, with other hands to appeal to for help, as well as feeling free of cultural demands and obligations that his fellows required from him. This kind of loss of contact would seem to be different from the "separation anxiety" of a psychogenic origin if it continued far enough, and it would be observed as a factor displaying mental attitudes and behaviour consonant with these as well as somatic symptoms. A sudden and severe traumatic shock can cut through all psychological defences like a knife and plunge the individual into a physically felt (psychological) danger-situation in which there are no hands to appeal to for help, either because there is literally no perceptual awareness of this in the depths of the fugue or because those in the situation are too dangerous to approach. Such cases are not uncommon. Are all fugues regressions? The loss of morale may be a slower but steady encroachment on the psychological defences (social-sense) until a point of regression is reached where delinquency, as atavism, begins to be displayed. In the previously diagnosed psychopathic personality his delinquency is not now unduly severely dealt with, and the individual is removed to a more suitable sphere.

I think that when Dr. Fairbairn writes of the neurotic Service men *en masse* needing an evangelist rather than a psychotherapist he unconsciously recognizes this atavistic tendency, for he insensibly slips from the psychological significance of morale into that of ethic and morals. Not that many psychotherapists would agree that pastoral psychopathy is desirable either in peace or war. By the terms of our own psychopathology we have all become social through being neurotic, since culture and civilization are emergent from repressions, inhibitions, and social conditioning. But in atavism the individual is heading either for the "animal" world of fear and danger in which he reacts according to the depths of his nature or toward throwing off the feeling of psychological guilt and being free of its repressing restraint. The return into civil life of men with loss of morale or delinquent tendencies is going to be a big problem, and the aim should be to avoid this. It is a psychiatric problem now, and will be after fighting has ceased. It is the biggest problem with regard to the treatment of Germany after the war.—I am, etc.,

London, N.W 8. JOHN MACKWOOD.

SIR,—In my article on the war neuroses (Feb. 13, p. 183) I endeavoured to express my views in a manner sufficiently simple and devoid of psychopathological technicalities to enable them to be understood by the average medical reader. There are certain misunderstandings, however, against which it is difficult for an author to safeguard himself—namely, such as may be introduced by a critic who displaces the original emphasis from one point to another, and treats in isolation particular items which are intended to form parts of a coherent whole. Such is the type of misunderstanding which finds its way into Sir Arthur Hurst's criticism (March 6, p. 299) of my views. Thus, in ascribing to me the view that a war neurosis is "the result of an attempt to restore emotionally the intra-uterine state of security which was rudely disturbed by the experience of birth," he is conferring the status of a major thesis upon what was intended rather to be of the nature of a philosophical aside. At the same time he completely ignores the basic clinical fact to which I draw attention—namely, that separation anxiety (i.e., anxiety over separation from home) is the central and universal symptom in all forms of war neurosis. No theory which fails to offer an explanation of this clinical fact deserves any serious consideration, and in my article I attempted to provide the explanation which seems to me best warranted by the evidence

According to my reading of the evidence the development of acute separation anxiety in a Service man is due to a regressive reactivation of a state of infantile emotional dependence which has never been properly outgrown. I also feel justified by the evidence in concluding that a war neurosis is characterized not simply by the appearance of certain symptoms but also by specific personality changes associated, both by way of cause and effect, with a lowering of morale. Since the cure of a war neurosis is not just a question of removing symptoms but one of reversing personality changes which are resistant to psychotherapy, and since morale is the very life blood of a military group, I further conclude that the cultivation of morale should take precedence over psychotherapy as a method of dealing with the problem of the war neuroses. Such are the "fantastic beliefs" in the light of which Sir Arthur considers it "easy to understand why Dr. Fairbairn finds that the war neuroses are resistant to *his* psychotherapy" (my italics). Here I must claim a greater measure of modesty than Sir Arthur appears disposed to grant me, for I can assure him that my opinion is based not upon the results of *my* psychotherapy but upon the results which I have observed, whether mine or anyone else's, and not least upon those observed in cases which had been previously returned to duty as cured.

I am not prepared to dispute the results obtained by Cooper and Sinclair during the siege of Tobruk under what Sir Arthur describes as "the most unfavourable conditions." My experience is admittedly confined to cases treated outside the zone of active warfare. I venture to suggest, nevertheless, that, however unfavourable the conditions at Tobruk might be from the standpoint of psychotherapy, they were conspicuously favourable from the standpoint of morale; and this consideration seems to me to support my general conclusion that the problem presented by the war neuroses is one of morale rather than one of psychotherapy. No results are of the slightest significance, of course, unless assessed in the light of a long-term (as against an immediate) follow-up, and it is only in the light of such a follow-up that the results obtained at the Seale Hayne Military Hospital during the last war by means of "simple psychotherapy in the form of explanation, persuasion, and re-education" can possibly be assessed.

Long-term results aside, however, I cannot refrain from raising the question whether such "simple psychotherapy" is really psychotherapy at all. Nothing that Sir Arthur has said convinces me that I was greatly in error when I felt driven to remark: "What these people need is not a psychotherapist but an evangelist." During the last war scientific psychotherapy had as yet barely emerged, but I fancy that in those days the evangelist had an easier task than he has now after twenty-odd years of complacency and disillusionment. I fancy, also, that it was easier to become an evangelist then.—I am, etc.,

Edinburgh. W. RONALD D. FAIRBAIRN.

Pleurisy and Pleural Effusion

SIR,—In the recent correspondence in the *Journal* on the above subject I see no mention of the subcutaneous tuberculin test, which I have been using with satisfactory results for the past 30 years. I begin with old tuberculin human (T) 0.0002 c.cm. If no reaction follows the dose is doubled again and again up to 6 doses, when the case is pronounced negative. If a distinct reaction follows any particular dose, the test doses are stopped, and the patient is advised to have sanatorium or a course of tuberculin treatment. The test doses are given once or twice a week according to convenience. I find that over 40% of these cases do not react to test doses, and can be set aside as non-tuberculous. This is a much larger proportion than could be rejected by von Pirquet or the intradermal tests.—I am, etc.,

Belfast. JOHN R. GILLESPIE.

Bagassosis

SIR,—The article by Drs. L. I. M. Castleden and J. L. Hamilton-Paterson on bagassosis (Oct. 24, 1942, p. 478) should stimulate interest in the occurrence of respiratory disorders among workers in sugar-cane factories in the Caribbean area. It is remarkable that these disorders have escaped notice up to the present.

During the grinding season air in a cane factory is filled with megass dust (or, as the authors term it, "bagasse" dust), and it is diffused throughout the surrounding air for a considerable distance, hence workers in the factory and people living in the neighbourhood inhale considerable quantities. Somewhat similar conditions are found in rice mills. Having noted that a considerable number of patients suffering from respiratory disorders, especially asthma, who had been referred to me for allergic tests worked in cane or rice mills, extracts of megass and of padi dust were made by Coca's method and the skin reactions of such patients tested by intradermal injection of 0.02 c.cm. Patients who worked in cane factories gave a positive reaction to the megass extract, and those in rice mills to the padi extract.

Early cases obtained relief and sometimes cure by avoiding the offending dust, but as this meant obtaining employment elsewhere, often at lower wages, they tended to return to their former employment, with consequent recurrence of symptoms. Treatment by desensitization with the appropriate extract was quite effective in the early cases, but old-standing cases complicated by chronic bronchitis and emphysema were less amenable to treatment. The latter were helped by small desensitizing doses of vaccines as recommended by Coke and Coke, followed by desensitization to the specific allergen. It would appear, therefore, that these disorders are, as the authors of the paper observed, the result of an allergic reaction. Not having had an opportunity to investigate these conditions in the factory, I am unaware to what extent workers in these industries are affected, but conversations with patients gave me the impression that it is not inconsiderable. The occurrence of respiratory disorders among workers in these industries requires investigation in all sugar- and rice-producing countries in order that methods for prevention may be devised.—I am, etc.,

P. A. CLEARKIN,

Georgetown, Demerara. Govt. Bacteriologist.

Eventration of the Diaphragm

SIR,—With reference to the article by Dr. A. J. E. Mills (Jan. 23, p. 97) under the above heading, there is not sufficient detail to make an exact diagnosis, but it would appear to be similar to that first described by Roemheld and also by Bergmann and Herz. The gastro-cardiac symptom complex first described by Roemheld is another cause for pains in the region of the heart. Gastro-intestinal disturbances result in an upward displacement of the dome of the left diaphragm, and this in turn causes displacement of the heart and larger blood vessels. In such cases there is always a large amount of air in the stomach or the large intestine, especially the left colonic flexure. Patients do not complain much so long as the stomach is empty. This explains, in the case described by Dr. Mills, the inability of the patient to play games for three or four hours after a meal. If he had tried to play games immediately after a meal he would, in all probability, have felt a pain in the heart area, back of the lower end of the sternum, and in the left shoulder. There is no mention of this patient's chest or abdominal measurements or details about his weight. In all probability he had put on some weight, and was also a mouth breather and was therefore unable to breathe deeply. No mention is made of blood pressure or blood-pressure curves in response to exertion; glycosuria is often seen in these cases, possibly due to diminished blood supply to the pancreas; there may have been anacidity, subacidity, fermentative dyspepsia, colitis, or aerophagia; avitaminosis B$_1$ is common. There is probably an atrophic condition of the diaphragm and often loss of tone in the abdominal muscles as well as inverted breathing. The hiccup is easy to account for and is caused mechanically. The vagus nerve runs through the narrow slit on either side of the hiatus oesophageus. In normal subjects there is ample room for the diaphragm to move up and down, but in old age or as a result of accumulation of gas in the abdomen the hiatus may be enlarged and become lax enough to have either some of the stomach pushed up or the oesophagus pulled down to form a kind of hernia causing irritation of the vagus. This would explain the disappearance of the hiccup when lying down.

This condition is fully described by Bergmann under the heading "epiphrenal syndrome." He carried out many experiments on animals by putting rubber balloons through the oesophageal hiatus and then filling them with air to stimulate the vagus in order to get the effect. These hernias have been demonstrated by *x* rays in 300 cases by Knothe at the Bergmann Clinic. There is also the work of Herz (*Die Sexuelle Psychogene Herzneurose,* Vienna, 1909) on phrenocardia connecting some of these cases up with psychogenic sexual neurosis. He substitutes the word "dyspnoea" for "respiratory block" in order to make a differential diagnosis between the neurosis connected with the diaphragm rather than from the lungs. His work was confirmed by Erb and others.

The position occupied during sleep is very helpful in making a differential diagnosis. Most of the patients sleep on the left side, whereas subjects of organic heart diseases usually sleep on the right. These patients also have hearts that are too small for their bodies and are subject to extrasystoles on sudden change of position. Only recently I saw a patient, aged 23 and home on seven days' leave from the Army, who complained of his heart: feeling of fullness and pain in the region of the heart, difficulty in breathing, nausea, and general feeling of anxiety. On examination (standing) the stomach was distended and there appeared to be a large amount of gas under the left side of the diaphragm. On examining him lying down I noticed the position of his apex beat moved upwards and outwards, and he was most uncomfortable, so much so that I decided to siphon off the air and gave him immediate relief.

These patients are often subjected to attacks of intercostal neuralgia, and one can see small capillary varicosities over the left costal arch, the supraclavicular fossae are frequently seen to bulge, and, according to Roemheld, there is often a deficiency of gastric secretion, and toxins are liable to be absorbed and injure the myocardium by visceral reflex effect.—I am, etc.,

London, W 1. J. E. O'LOGHLEN.

Staffing of Miniature Mass Radiography Units

SIR,—The machines for the examination of the civilian population have been designed for the express purpose of radiographing men and women at the rate of 5,000 a week or 250,000 a year. Naturally it will take time and organization to ensure that each unit will be fed to capacity and at a uniform rate.

The unit may be found to be easy to take to pieces and to reassemble, but difficult to transport from one centre to another, and the best choice of site for its operation may be found only by trial and error. It seems that in the larger towns the first group of machines is likely to be static, and should therefore be erected in a convenient site, where large numbers of the population pass or congregate. The need for adequate dressing-room accommodation has been stressed by Dr. Henderson (Jan. 16, p. 81), and heating and cloakroom attendance should not be overlooked. Sites that automatically suggest themselves might be the London railway termini, the larger stores, or air-raid shelters accommodating some thousands of persons. Such sites might appeal more to the man in the street than, say, the out-patient department of a large hospital.

The method of stamping the identity card, practised abroad, would seem a convenient one to remind the owner of the date when re-examination should be carried out, and to enable the patient's doctor to obtain any information he may require regarding the examination.

It will be found that each machine will be capable of taking a considerably larger number of miniature films than any small group of medical men is able to interpret, and it will be found necesary to make provision for the interpretation of a large surplus of miniature films. It makes little difference whether such interpretation is carried out by physicians or radiologists so long as it is accurate, and I think Dr. Henderson's suggestion that each series of films should be examined by two observers is a wise one, and would suggest that the reports should be made independently and should be correlated by a third observer. It is understood, of course, that every suspected abnormal finding would be checked by routine radiography prior to a clinical examination. Personally I feel that many interpreters would be willing to carry out, say, 500 interpretations per week in their own hospitals or homes provided they were kept informed of the results of the subsequent findings.

The success of the scheme will depend largely on the co-operation of the public, who will need to be informed by the Ministry of Health of its object through the cinema and Press. —I am, etc.,

London, S.W.3 J. V. SPARKS.

Trichlorethylene Anaesthesia

SIR,—Trilene has recently been accused of having two faults: first, that it is liable to be decomposed into phosgene by the heat of the diathermy apparatus; and, secondly, that it may cause auricular fibrillation.

As regards the formation of phosgene, this is no more likely to happen with trilene than with chloroform. In spite of the fact that chloroform is freely used in the presence of fires, flames, and sparks the references in the literature to phosgene formation are rare. Phosgene causes lacrimation and coughing in half the concentration required to do any harm. Lukis describes a case in which coughing and lacrimation were caused by the use of open chloroform in a small room where there was a coal fire and gas jets. The symptoms quickly subsided when the window was opened.

As regards auricular fibrillation, I had a case this morning of a healthy young woman who was being anaesthetized with N_2O 70% + O_2 30% and trilene for dissection of her tonsils. After blind nasal intubation the pulse was normal in rhythm and rate, but 5 minutes later it became faster and grossly irregular. At that time anaesthesia was deeper than necessary (plane 3). Anaesthesia was lightened to plane 2, and 10 minutes later the pulse returned to its normal rate (80 per minute) and rhythm. Anaesthesia was continued for another 15 minutes with the same agents without further incident. There was no cyanosis.

Transient alterations in the heart's action are found to occur not very uncommonly during all kinds of inhalation anaesthesia if they are watched for sufficiently carefully, and not enough data have been gathered to enable a decision to be made as to whether or not trilene is a worse offender in this respect than ether.—I am, etc.,

Colchester. DOUGLAS CLENDON.

Little Audrey and the Doc

SIR,—Little Audrey had a friend called Emma, who awoke one bright post-war morning with a very bad cold. Her mother, who knew all the answers, said she was to get out of her nice warm bed at once, dress herself, and come to the Health Centre. Emma tried crying, but it didn't work, so she got out of bed and shivered, and presently shivered still more in the rain at the bus stop. She got her own back by coughing all over everyone in the bus, which was very full, because a lot of other people with impetigo, sprained wrists, scabies, rheumatic fever, and what-have-you were going to the Health Centre too. When they got there Emma and her mother sat in a beautiful big waiting-room for hours and hours, while her mother wondered what to do about the shopping and the washing, and got crosser and crosser. Emma just went on coughing and wheezing, till, by-and-by, a man in a white coat said they couldn't see Dr. Smith because it wasn't his day, so Emma just yelled and said she wouldn't see anyone else, and the man said she was a very naughty girl and took her into a room where he examined her very carefully and wrote out a lot of forms in duplicate. Then they had to wait again, because Emma was to have her chest *x*-rayed and her sputum typed and her blood count done. So they had a bun instead of dinner, and Emma went on shivering and got red in the face and sweated, and Emma's mother got crosser and crosser, and Emma cried again, till, about tea-time, another man in a white coat said it was all right: Emma had pneumonia and must go to hospital, and that the ambulance would be along soon.

It turned out to be a very interesting case, because Emma got an empyema, and had all sorts of operations and tests and had ever so many notes and reports all in duplicate, except for some that were in triplicate, and she went to a lovely convalescent home; and her mother was able to get on with the washing and the shopping without a coughing child in the house.

Little Audrey (she was Emma's friend, you remember) woke up with a wheezy cold, too; but her mother was old-fashioned and just rang up Dr. Brown, who had brought little Audrey into the world and knew her colds of old. Dr. Brown came round, and opened the windows and felt the hot-water bottle. Then he tickled little Audrey, who loved him and called him doc-doc, which was most unscientific, till little Audrey laughed and laughed and laughed. She laughed so much that she laughed all the germs out of her chest and got well the next day, which was all very dull, because no one did anything really clever or wrote up any notes in duplicate. —I am, etc.,

Ashtead, Surrey W. EDWARDS.

I. L. Hamilton-Paterson and L. I. M. Castleden (*Brit. Heart J.*, 1942, **4**, 103) record three cases of infracardiac tumour—namely, a sarcoma of the right auricle in a woman aged 45, a pseudo-myxoma of the left auricle in a man aged 46, and an aneurysm in a man aged 27, which in life produced signs and symptoms attributable to Ayerza's syndrome, mitral stenosis, and pulmonary stenosis respectively. The following classification of heart tumours is suggested: (1) benign tumours due to organization of blood clot—pseudomyxomata; (2) malignant tumours arising from the mesenchymal elements of the heart wall; and (3) benign congenital tumour

Obituary

JOHN F. FERGUS, M.A., M.D., F.R.F.P.S.Glasg.

It was with great regret that the medical profession in Glasgow learned of the death on Feb. 18 of Dr. John F. Fergus in his 78th year. Dr. Fergus belonged to a distinguished medical family in Glasgow, his father being the late Dr. Andrew Fergus (an intimate friend of Lister when in Glasgow), one-time President of the Royal Faculty of Physicians and Surgeons, and his elder brother, Dr. Andrew Freeland Fergus, the well-known ophthalmologist.

John Freeland Fergus was educated at the High School of Glasgow and Glasgow University, graduating M.A. in 1883, M.B., C.M. with high commendation in 1888, and M.D. in 1897. After graduating he was house-physician at the Western Infirmary, and continued his studies at Vienna and Jena. Throughout his professional career Dr. Fergus was much concerned in public medical affairs. He represented the Royal Faculty on the board of management of the Glasgow Royal Infirmary, and for several years was convener of the medical committee. He also represented the Royal Faculty on the board of the Royal Technical College of Glasgow, and gave good service in a similar capacity to the Broomhill Home for Incurables and the West of Scotland Seaside Homes, Dunoon. Always actively interested in his university, he was largely instrumental in securing the excellent playing fields at Anniesland, and as an assessor on the university court, elected by the general council of the university, he played an important part in the government of the university. In all of these positions he showed a proper business sense, and was actuated by a spirit of fair-mindedness and anxiety for the welfare of the institution. In the last war he was a visiting physician to the Springburn-Woodside Red Cross Hospital, and after the war assisted in the teaching in the Royal Infirmary as assistant to the Muirhead professor of clinical medicine.

Dr. Fergus was a most ready writer, both in prose and in verse. He contributed to the *Glasgow Medical Journal* papers of purely medical interest as well as some on the history of medicine. "Some Medicines of our Ancestors" was published in that journal in 1918, and about the same time his paper on "The Medical School of Salerno" was read to the Royal Medico-Chirurgical Society. Perhaps it was as a poet and reciter of his own poems (though he maintained that they were no more than "trivial verses") that Dr. John Fergus was most widely known to the profession and the public of Glasgow. He was the author of many topical poems much in request at medical and other social gatherings, and was a member, sometime vice-president, of the Glasgow Ballad Club. His volume entitled *Carmina Urbis et Ruris* contains compositions for meetings of one of Glasgow's favourite social medical societies—the Town and Country Club. In the last war he published a small volume, *The Sodger and Other Poems*, the proceeds of the sale of which were devoted to the Sailors and Soldiers Families' Association. The *Fancies of a Physician*, published in 1938, is a representative collection of some most admirable verse, "medical and otherwise," grave and gay, in Scots and in English, the most noteworthy celebrating the Royal Faculty and its founder, Maister Peter Lowe, the Royal Infirmary, and the Royal Medico-Chirurgical Society. He leaves a wife and son and daughter, to whom sincere sympathy will be extended.

Dr. R. H. Tasker died at sea in the latter part of November, 1942, as the result of enemy action, at the age of 50. Ronald Henry Tasker began his medical studies in the University of Bristol and did his clinical work at the Bristol General Hospital. In 1917 he qualified M.R.C.S., L.R.C.P., spending the next two years with the Fleet as temporary surg. lieut., R.N. He was house-surgeon and house-physician at the Bristol General Hospital and filled resident appointments at Herefordshire General Hospital and at Ham Green Hospital, Bristol. In 1926 he became medical officer to the Burmah Oil Company and entered with enthusiasm into life in the East. For 16 years he rendered able and devoted service in various parts of Burma, and at the time of the Japanese invasion was in charge of the company's hospital at Syriam, Rangoon. Here he remained while the demolitions were completed, afterwards making a precarious escape to India. He finished the remainder of his term of service in Assam, and was returning to England when his ship was torpedoed in the South Atlantic. In 1930 he married Dr. Dorothy Buckmaster, daughter of the late professor of physiology of Bristol University, and to her and to the young son and daughter the sympathy of the profession will be extended. A colleague writes: It is difficult to convey any idea of Ronald Tasker's vivid and joyous personality. Everything humdrum and petty was dispelled by his unforced gaiety and abounding good nature. His was the great gift of laughter and the superlative merit of communicating happiness to others. Yet he was conscientious to a degree in his professional work, in which he showed great skill as a surgeon, and he had a remarkable athletic career. Ronald Tasker was a county player in association football, tennis, and badminton. In his student days he played, as an amateur, for Bristol City, then in the Second Division of the Football League. While recovering from a severe football injury he studied croquet and became a first-class player. His wife shared his love of games, and for many happy years they were a formidable pair in tennis and badminton tournaments in Burma. Possessed of amazing energy and concentration, for both work and play, he found time to be widely read, especially in comparative religion and anthropology. His friendship was actuated by sincerity and loyalty, but never by expediency. Thus there were those in many walks of life who were proud to call him friend, and would cordially agree that they owed to him some of their happiest hours. There were 54 in the lifeboat in which he died, after being many days adrift, and one of the two survivors has told me the tragic story of his passing. An inspiring colleague, a gallant sportsman, and a true friend.

Dr. Donald Buchanan, who died at Eltham on Jan. 18 at the age of 63, came of a family which had lived on the Isle of Barra for many generations. Buchanan studied medicine at Aberdeen University, where he graduated M.B., Ch.B. in 1908. He took the D.P.H. of the University of Birmingham in 1910, proceeding M.D. in 1911. Some years before the outbreak of the last war he was appointed port health officer at Singapore, and later at Port Moresby, New Guinea. From the latter post he returned to this country to serve with the R.A.M.C.—he was attached to the Territorial Army before he went abroad—and distinguished himself in France, being mentioned in dispatches several times. When the war ended he went to Edinburgh, where he took the F.R.C.S. He then settled in South-East London and built up a large practice there. Last August he published *Reflections on the Island of Barra*. An able practitioner, he will be sorely missed by the many patients who looked on him not only as their medical adviser but as their friend in need.

We regret to announce the death on Feb. 19 of Dr. T. Anstey-Chave of Redhill. Born at Hereford in 1870 and educated at the Cathedral School, Thomas Anstey-Chave first joined a firm of London stockbrokers, but finding that City life was deleterious to his health he decided to take up medicine, which was his original interest. From St. Bartholomew's Hospital he qualified M.R.C.S., L.R.C.P. in 1896, and four years later took the M.B.Lond. and the F.R.C.S.Ed. He was then appointed house-surgeon at the Hereford General Hospital, and after holding two assistant posts at mental hospitals he took a share in a general practice in Cardiff, where he stayed for 13 years. His health, however, gave way and he went abroad for some months. When he recovered he took over the practice of Dr. Drake of Redhill, developing the radiological work there, and became an acknowledged authority in the district. He was radiologist to the East Surrey, Sevenoaks, and Dorking Hospitals, and had several other radiological appointments. Dr. Anstey-Chave had been a member of the B.M.A. since 1899. He represented his Division at the Annual Meetings in 1917 and 1918, and was secretary for the Reigate Division in 1922 and chairman from 1925 to 1927. He was also secretary of the Surrey Medical Benevolent Society from 1922 until his death.

Dr. James Mair Rutherford, whose death, we regret to announce, took place at Bristol on Feb. 22, followed his father's profession and also his specialty, for he was the son of the late Dr. James Rutherford, medical superintendent of the Crichton Royal Institution, Dumfries, and for the last 34 years had been medical superintendent of Brislington House, a private mental hospital near Bristol. Rutherford qualified M.B., C.M. at Edinburgh in 1894, took his membership of the Royal College of Physicians of Edinburgh in 1906, being awarded the Gaskell Prize, and became a Fellow in 1909. He was senior assistant physician at the Royal Asylum, Morningside, before he went to Bristol. Of athletic build, Dr. Rutherford excelled at hockey and golf, and was also a first-class shot. He had been a member of the B.M.A. for 46 years.

Medical Notes in Parliament

Diphtheria Outbreak traced to Milk Supply

Sir FRANCIS FREMANTLE on March 11 asked the Minister of Health whether the outbreak of diphtheria in East Yorkshire, traced to new clean milk from a farm, was due to infection the spread of which could have been prevented by pasteurization, and what action had been taken to avoid such danger in future. Mr. ERNEST BROWN replied that the spread of infection in the case referred to would have been prevented by pasteurization. Only one cow was kept on the farm concerned, and the sale of milk from this farm had been ended.

Health in the West Indies

Colonel OLIVER STANLEY opened, on March 16, a debate on colonial administration in the West Indies. He said the section on health in the Stockdale report well set out the health problems which would have to be met. In many ways the most important was the suggestion of the health community system, an attempt to take into rural, scattered communities the health advantages normally found in an urban, highly populated area. The Colonial Office had given authority for a large-scale experiment in this health community system in the Jamaica parish of St. Catherine.

Mr. CREECH JONES referred to malnutrition and doubted whether the proposals of the report were enough to deal with the squalor and dreadful housing in most of the West Indian colonies. Dr. HADEN GUEST cited evidence from the Committee on Nutrition in the Colonial Empire that in Jamaica rickets was frequently found among younger school children. The health problems of the West Indies were insoluble without adequate nutrition. To erect a costly medical structure on the basis of the poverty of the West Indies would give the doctors appointed an impossible task. Dr. MORGAN suggested a mobile team of medical experts ready to go to islands where epidemics had broken out or to others where water supplies needed attention. The Stockdale report did not mention or did not emphasize hookworm disease because Government policy made that disease endemic. There was no decent scheme, except in Trinidad, for proper latrines to prevent the infection. Medical officers engaged in preventive work had no opportunity for doing their work properly. Leprosy could be abolished in the West Indies in a generation. Many sufferers from leprosy filtered back to this country by means of retired officers from the Colonies and now tramped the streets of Great Britain unrecognized.

Dermatitis in Mining Industry

On March 17 Mr. BERNARD TAYLOR asked what steps were being taken to deal with dermatitis in the mining industry. Mr. TOM SMITH answered that any epidemic of this disease, however small, reported among a particular set of workers at a particular mine was investigated in relation to the working conditions, and ameliorative measures taken so far as possible. The large majority of the cases appeared to be sporadic in the sense that they comprised, in ones and twos, workers having many different occupations and employed at many different mines. These cases presented a difficult problem which would be further investigated through the medical officers of mines who were taking up their duties in the coalfields.

Vaccination in the Army.—Answering Mr. Viant on March 16 Sir JAMES GRIGG said vaccinations in the Army were performed in accordance with instructions essentially similar to those issued by the Ministry of Health to public vaccinators. Successful cutaneous vaccination must of necessity lead to the formation of scar tissue, but scars resulting from present methods of vaccinating soldiers were generally very slight.

Medical Regrading and Army Employment.—In a reply on March 16 Sir JAMES GRIGG said a man's physical condition tended to improve as a result of Army training, and in a normal case the medical officer who had watched the man at work could properly determine when he was fit for a higher medical grading. This arrangement would, however, shortly be modified. Army selection centres were being instituted. Eventually all soldiers whose change of medical category entailed a change of employment would pass through these centres and there be classified and allotted to the duties they could best perform. Men suffering from defects which could be cured would be given special remedial training

Public Health Propaganda.—Asked how many posters in the series entitled "Coughs and Sneezes Spread Diseases" had been issued by his Department for publication, Mr. BROWN said on March 16 that in the current campaign which began last October 152,170 posters and vehicle bills had been issued at a cost of £12,600.

The Services

Capts. O. I. Green, W. N. Hine, and E. D. V. Nicoll, R.A.M.C., have been awarded the M.C. in recognition of gallant and distinguished services in the Middle East.

The name of Lieut. (now Capt.) D. P. G. Paisley, R.A.M.C., was included in a list of officers and men commended for brave conduct in a *Supplement* to the *London Gazette* dated Feb. 17, 1942. We regret that, through an oversight, this item of news was not published in the *Journal* at the time.

Temp. Surg. Lieut. W. D. G. Troup, R.N.V.R., has been mentioned in dispatches.

The annual general meeting of the members of the Auxiliary R.A.M.C. Funds will be held at 11, Chandos Street, W., on Monday, April 5, at 6 p.m., when the annual report and financial statement for the year ended Dec. 31, 1942, will be presented and officers elected for 1943.

CASUALTIES IN THE MEDICAL SERVICES

Major W. L. BROOKES, Indian Medical Department, is included as "died" in an India Office Casualty List published on March 15.

Temp. Surg. Lieut. JACK BLOOR HOUGHTON, R.N.V.R., is included as "missing, presumed killed," in an Admiralty Casualty List published on March 13. He was born on March 20, 1917, and received his professional education at King's College Hospital, qualifying M.R.C.S., L.R.C.P. in 1940. Before entering the R.N.V.R. in July, 1941, he held an appointment at the Blind School Hospital, Leatherhead, Surrey. In Aug., 1942, he was mentioned in dispatches for distinguished services in convoys to Murmansk. He was a member of the B.M.A. and his home was at Woodthorpe, Nottingham.

Lieut. EDWARD RAYMOND STONE, R.A.M.C., is included as "killed" in an Army Council Casualty List published on March 17. He was born on March 5, 1913, and graduated M.D.Georgetown in 1939. He entered the U.S.A. Section of the R.A.M.C. in Aug., 1941. His home was at Washington, D.C.

Prisoners of War.—Lieut. W. G. Anderson, I.M.S., Acting Major A. M. Best, I.M.S., Capt. T. R. S. Cormack, R.A.M.C., Acting Major A. C. Glendinning, I.M.S., Capt. D. W. F. Gotla, R.A.M.C., Lieut.-Col. C. W. Maisey, R.A.M.C., Col. J. M. Mitchell, O.B.E., I.M.S., Capt. L. Sefton, R.A.M.C., Surg. Lieut. D. R. Syred, R.N.V.R.; Surg. Lieut. J. C. Wyatt, R.N.

Missing.—Capt. J. A. Perkins, R.A.M.C.

Medical News

Sir Hugh Lett will deliver the Thomas Vicary Lecture at the Royal College of Surgeons of England, Lincoln's Inn Fields, W.C., on Friday, April 2, at 4 o'clock. His subject is "Anatomy at the Barber-Surgeons' Hall."

The Council of Epsom College will in July award a France Pension of £30 a year to a necessitous medical man, fully 55 years of age, who has been registered for five years, and who is in need of help. The Council will also award St. Anne's Scholarships to girls attending Church of England schools, who must be fully 9 years of age and be orphan daughters of medical men who have been in independent practice in England or Wales for not less than five years. The value of each scholarship is dependent upon the means of the applicant and the locality and fees of the school selected. Educational grants will also be available from the Sherman Bigg Fund for children of either sex. These are not restricted to orphans or to members of any religious denomination, but candidates must be of public school age and in need of such help. Forms of application for the vacant pension and for the scholarships and grants can be had from the Secretary's Office, Epsom College, Surrey, and must be completed and returned by April 30.

A postgraduate lecture and demonstration on living models of clinically approved means of contraception will be held at the C.B.C. Mothers' Clinic, 108, Whitfield Street, W.1, on April 1 at 2.30 p.m. Applications to attend should be sent to the secretary beforehand.

At a recent meeting of the Central Midwives Board for Scotland Prof. R. W. Johnstone and Prof. James Hendry were elected chairman and deputy chairman respectively for the ensuing year.

Surg. Rear-Admiral C. P. G. Wakeley will give a lecture on "Blast Injuries in Total War" at Chichester County Hall on Thursday, April 1, at 2.30 p.m.

Air Commodore Geoffrey Keynes, R.A.F.V.R., will give a discourse on "The History of Blood Transfusion" at the Royal Institution, 21, Albemarle Street, W., on Friday, April 9, at 5 p.m.

The annual general meeting of the Institute of Hospital Almoners will be held at St. Ermin's Restaurant, Caxton Street, St. James's Park, S.W., to-day (Friday, March 26) at 6 p.m., when Prof. James Mackintosh will give an address.

A conference on education, arranged by the Association of University Professors and Lecturers of Allied Countries in Great Britain, will be held at the Royal Institution, 21, Albemarle Street, London, W.1, on April 10. The two subjects for discussion will be the function of a university in a modern community and methods of practical co-operation between Allied universities in the future. Tickets of admission may be obtained from the conference secretary, 40, Queen's Gate, S.W.7.

Miniature mass radiography units are to be set up in Edinburgh, Glasgow, and Lanarkshire. Mr. Tom Johnston, announcing this decision, also stated that the scheme providing allowances for dependants of patients undergoing treatment for tuberculosis was nearly complete. Maintenance payments would include sums for dependent children according to age and payments to meet such special items as high rents, insurance, mortgage charges, etc. The scheme might have to be reviewed in the light of plans arising out of the Beveridge report or out of any general arrangements for rehabilitation.

Proposals for the establishment of a department of neurology in association with Manchester University are being submitted to the Nuffield Trust by the Provincial Hospitals Regionalization Council at Manchester.

Mr. G. W. Blomfield, F.R.C.S., has been appointed director of the Radium Centre, Sheffield.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* a rise in the incidence of whooping-cough, 90 cases, and of acute pneumonia, 77 cases, and decreases in the notifications of measles, 682, and dysentery, 28, were the chief features of the returns during the week. The fall in the notifications of measles was largely due to experience in the North. The largest decreases were those of Yorks North Riding 361, Yorks West Riding 277, Durham 232, Lancashire 184, and Yorks East Riding 149. In the South with a few exceptions the incidence continued to rise, the most notable increases being Essex 157, Gloucestershire 135, Devonshire 85, Sussex 82, Berkshire 73, and London 60.

There were 79 deaths from influenza in the 126 great towns. This is the third consecutive week that a fall has been recorded, and it seems that the danger of a possible large epidemic has passed. During the first nine weeks of this year 887 deaths were recorded in the great towns, compared with 644, 1,683, 3,489, 2,053, 559, and 6,679 for the corresponding period of the six preceding years.

During the week 68 cases of dysentery were reported, 28 fewer than in the preceding week and the lowest weekly total for the past six months. Lancashire with 18 cases and London with 12 accounted for almost half the total notifications. The only other notable local fluctuations in the incidence of infectious diseases were for pneumonia, rises of 45 and 40 being recorded in Durham and Wales respectively, and a fall of 78 in Yorks West Riding. In London there was an increase of 52 in the notifications of whooping-cough.

In *Scotland* there was a sharp rise—from 10 to 22—in the number of cases of cerebrospinal fever in the city of Glasgow. The increase in the notifications of dysentery was due to the experience of the city of Aberdeen, where 12 cases were reported; 11 were recorded in Glasgow, and the two cities together accounted for two-thirds of the total. There was another small rise in the incidence of measles in Glasgow, where 317 of the 477 notifications were recorded.

In *Eire* the chief feature was a decrease of 23 in the notifications of diphtheria.

The Week Ending March 13

The returns of infectious diseases in England and Wales during the week included: scarlet fever 1,907, whooping-cough 1,864, diphtheria 794, measles 19,799, acute pneumonia 1,315, cerebrospinal fever 86, dysentery 78, paratyphoid 4, typhoid 4. Deaths from influenza in the great towns numbered 69.

No. 9

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended March 6.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1.
ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated
Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.
ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.
TELEPHONE No.—B.M A. and *B.M.J.*: EUSTON 2111.
TELEGRAPHIC ADDRESSES.—EDITOR, *Aitiology Westcent, London;* SECRETARY, *Medisecra Westcent, London.*
B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Iron in Diet or as Drug

Q.—*If hypochromic anaemia is said to result from deficiency of iron in the diet, how is it that an increase in dietetic iron makes no improvement in hypochromic anaemia?*

A.—It is difficult to give much more than maintenance requirements of iron by diet alone. In hypochromic anaemia the marrow is abnormal and often requires stimulation by a large dose of iron before it will respond. This has been called the "threshold phenomenon"

Cramp in an Elderly Woman

Q.—*What is the cause of cramp in elderly women? What is the best way to prevent them and to relieve them?*

A.—Varicose veins, arteriosclerosis, and diabetes are probably the commonest causes of cramp in elderly women. Treatment is primarily of the causative condition. Relief may be obtained from warm leg baths twice daily, nicotinic acid 50 mg daily, and resting with the feet up.

Enterospasm and Spastic Colitis

Q.—*I would be grateful for suggestions in treatment of a case of severe and frequent enterospasm in a man of 50 who is also suffering from rheumatoid arthritis. He has had every sort of orthodox and unorthodox treatment for the latter, which is thought to be allergic and not infective in origin. For the enterospasm he has had belladonna and atropine in all forms, and ephedrine. He has had wash-outs. It would be very difficult to arrange for psychological treatment.*

Q.—*There is an increasing tendency nowadays to classify "spastic colitis" as an allergic disease. Is there any evidence as to the nature of the allergen, and is it possible to desensitize a patient, as in asthma? Apart from this, what is the best treatment, and what advice should one give a patient with regard to war work?*

A.—Enterospasm is never a primary condition. Its treatment therefore depends upon the discovery and removal of the cause Atropine before meals in maximal dosage for the individual, with codeine if there is diarrhoea, relieves the discomfort and pain. The causes of enterospasm can be summarized as follows:

1. Acute intestinal irritation with or without actual enteritis and/or colitis (*a*) Food poisoning. (*b*) Excess raw fruit, especially unripe, or raw vegetables, especially wartime salads of vegetables not commonly eaten raw.
2. Abuse of purgatives: extremely common.
3. Intestinal carbohydrate dyspepsia: very common. Associated with distension of colon and excessive flatus, the passage of which gives relief. Treatment by restriction of potatoes and other root vegetables, and rice.
4. Excessive smoking.
5. Allergy: recurrent very short attacks of pain which may be associated with diarrhoea, vomiting, rhinorrhoea, or urticaria.
6. Lead poisoning
7. A rare form of tabetic crisis.
8. Organic disease of colon. (*a*) Colitis; always diarrhoea with mucus and generally blood in stools. (*b*) Diverticulitis; pain and tenderness, especially left iliac fossa; normal stools. (*c*) Carcinoma.

There is no such clinical entity as "spastic colitis." True colitis is always associated with spasm; it is primarily infective, occasionally toxic, and never allergic Spastic colitis is sometimes used as a synonym for "muco-membranous colic" which has become very rare in recent years. This too is not a colitis, as sigmoidoscopy shows a healthy mucosa and the mucous shreds and casts contain no inflammatory material. It is a form of colon spasm occurring in nervous individuals, generally women, and associated with excessive secretion of mucus. It is always accompanied by constipation, which should be treated with paraffin and isogel but no aperients or enemas. In rare instances it is caused by specific foods and may then be allergic; such foods should be avoided, but desensitization is useless. The more war work the patient does the better, as it helps him to become less bowel-conscious.

LETTERS, NOTES, ETC.

Double Beds and Scabies

Dr. FREWEN MOOR (Norwich) writes: A few months ago I pointed out that the spread of scabies was largely due to the use of double beds, and that the almost complete immunity of the rich was due to their use of single beds for children and unmarried adults. Scabies is only an extreme case of the general law that infectious and contagious diseases are disseminated by close and prolonged contact. Who in his senses would share a bed with a person suffering from influenza or even a cold in the head, unless he definitely wanted to catch it? And yet that is done as a matter of course in the great majority of English homes. After the war there will be an enormous demand for furniture to replace what has been destroyed and for the setting up of new homes, and now is the time to launch propaganda for single beds. Of course these will cost more, but people might be persuaded to go to the extra expense if the advantages were pointed out to them in good time. I do not know whether the houses built by the public authorities always have bedrooms big enough to take two or three single beds instead of a double one, but this is a matter to be considered when new houses are being planned. A lot of attention is paid to conditions in factories, but unsatisfactory hygiene in the home has hardly been touched, although it is really more important. We doctors are too much inclined to accept existing conditions and to treat the results. Now is a favourable opportunity, unlikely to recur, to change one bad old custom.

Nasal Defence

Dr. ALEXANDER FRANCIS (London, W 1) writes: Dr. Octavia Lewin (Feb. 6, p. 178) is right in thinking that the nose supplies one of Nature's most important lines of defence, but wrong, I maintain, in regretting that coupons are now necessary for handkerchiefs. There is nothing, except the local application of preparations containing adrenaline and ephedrine to the nasal mucous membrane, which does more damage to the proper functioning of the nose than frequent nose-blowing. Resistance to catching cold depends chiefly upon active circulation. Nose-blowing interferes seriously with the proper circulation in the nose; it drives the blood into the turbinated bodies, causing nasal obstruction and increased secretion, thereby providing a good example of a vicious circle: the more one blows the more the secretion, the more the secretion the more one blows. Anyone can produce a condition of nasal obstruction and catarrh by sufficient nose-blowing, whereas nasal obstruction, if not too well established, and hypersecretion can be removed by deep nasal inspirations, which draw the blood away from the mucosa and promote a more active circulation. To teach children to blow their noses constantly is a most harmful practice, as it leads to the engorgement of the turbinated bodies, to increased nasal secretion, and to the development of adenoids.

Filaria Worm in Eye

Dr. ANDREW SIMPSON (Hawick) writes: I was interested in the accounts by Squad. Leader M. C. T. Reilly and Dr. C. R. Duncan Leeds of the removal of filaria from the eye. I have had to remove a worm from a patient's eye on three occasions, the last being a few weeks ago. She was in Nigeria for some time, but left there 5 years ago, and says that she left the infective area 7 years ago. She had no trouble until 1939, when, following swellings in various parts of the body, she appeared with a worm wriggling in the subconjunctival tissue. On each of the occasions it was about 5 a.m., and I found that the application of tropocaine (Waite), while anaesthetizing the eye completely, had no effect on the worm. A straight needle held in artery forceps was used to pierce the conjunctiva about the centre of the worm, and, impaling it, to withdraw it through the incision. The patient tells me that her husband has had them removed from his eye with darning needles, and certainly this method seemed very easy Perhaps I was lucky that on each occasion the worm was so accessible. It was about 35 mm. long each time and a *Loa loa.* The time factor seems to bear out a longer stay in the body than is usually held as its life, while there are continuing small swellings in this case in the breast and particularly the legs.

Nocturnal Cramp

Dr. LIONEL J. PICTON writes: The old "sovran remedy," one-tenth of a grain of calomel at bed-time, should not be forgotten. It may be guaranteed to obviate the cramp from the second night of its use. How it acts I know not; but at a guess it may be a catalyst.

ASTHMA IN CHILDHOOD*

BY

Sir ARTHUR HURST, M.A., D.M., F.R.C.P.

Consulting Physician to Guy's Hospital, and Chairman of the Medical Advisory Committee, Asthma Research Council

"I have suffered under the Tyranny of the Asthma, at least, Thirty years; and therefore I think myself to be fully informed in the History of that Disease; And since I have practised Physick, I have made many Trials for the Relieving and Preventing of the Fits; and out of Compassion to those Miserable Patients, I design to relate what I have found useful both to my self and others." Thus wrote Sir John Floyer in his *Treatise on Asthma* in 1698. Floyer's patient, Dr. Johnson, relates how he "panted on" till his death at the age of 83, thirty-six years later. Though my experience of asthma extends over only forty-eight years, compared with Floyer's total of sixty-six, it is perhaps this rather extensive experience which prompted your President to invite me to open to-day's discussion.

The Asthma Diathesis

Many years ago I defined asthma as the reaction of an over-excitable bronchial system, including the medullary centre, the vagal nerve-endings, and the bronchial musculature and mucosa, to blood-borne irritants and to reflex and psychical stimuli, and I see no reason for altering that definition. The irritable bronchial system, which constitutes the asthma diathesis, is a congenital and often inherited constitutional abnormality. It results in the vagal constituent of the bronchial nervous system being predominant over its sympathetic partner. In the presence of this diathesis certain allergens and reflex and psychical stimuli, which have no effect on normal individuals, give rise to spasm of the bronchial muscles, often associated with hyper-secretion of the bronchial mucous glands, together with congestion of the bronchi, which is the natural accompaniment of their excessive functional activity. Associated with the physical side of the asthma diathesis there is probably a psychological side, which manifests itself in a special type of personality. It is extremely difficult to decide how much of the "asthma personality" is a result of over-protection by too anxious parents—the great importance of which I first learnt from Dr. H. C. Cameron—and how much is constitutional. Rogerson (1937) has, however, given good reasons for believing that there is a constitutional element, which manifests itself in intelligence above the average, over-anxiety, and lack of self-confidence. At the same time the asthmatic child is often aggressive and dominating.

The constitutional factor in asthma shows remarkable variations at different times. A patient may be almost constantly asthmatic for weeks together and then have a period of complete freedom, when he can expose himself with impunity to all the allergens to which he is usually sensitive, eat big meals just before bedtime, take unlimited exercise, and face psychological difficulties which on other occasions would cause severe attacks. It is often impossible to recognize what leads to these periods in which the bronchial system appears to have lost its irritability. But there is no doubt that the more completely attacks are prevented by removing all known exciting causes the less irritable does the bronchial system become. One might be tempted to believe that the cure of asthma is not to have it; but unfortunately this is not true, as even after long periods of freedom the diathesis is still present and the asthma may recur. It is, however, a fact that if a child can be kept completely free from asthma for a couple of years he is quite likely to remain free for the rest of his life.

Biochemical Causes: Allergy

In recent years so much attention has been directed to the question of hypersensitiveness to proteins and other chemical substances in asthma that there has been a tendency to regard "allergy" as the one essential factor. The truth is, however, that an individual who is hypersensitive to one or more proteins does not suffer from asthma unless he has the asthma diathesis. In its absence he may have hay-fever, various cutaneous disorders, or gastro-intestinal attacks if his nose, skin, or alimentary canal respectively is hypersensitive, or he may have no resulting symptoms of any kind. There is no doubt, too, that many asthmatics are not allergic at all, their attacks being caused only by reflex and psychical stimuli. It is none the less of the greatest importance to give every asthmatic an exhaustive cross-examination with the object of discovering whether any or all of his attacks are due to his being allergic to some food, animal emanation, pollen, dust in his home or working place, or orris-root powder. Hyde Salter described in the second edition of his admirable monograph on asthma, published in 1868, how his detective work had demonstrated the asthma-producing influence of cats, horses, feathers, guinea-pigs, rabbits, sheep, deer, hares, and cattle in some of his patients.

When I was in America in 1919 I visited Chandler Walker, as I had been told that he had devised a method of recognizing the allergens to which an asthmatic was sensitive by means of skin reactions, and it was hoped that this would revolutionize the treatment of asthma. (The method was, however, not really new, as Blackley had applied pollen to the forearm "after the skin was abraded as in the ordinary mode of vaccination" in cases of hay-fever and hay-asthma in 1865, and it had also been tried in hay-fever by Noon and Freeman.) Walker demonstrated his methods and gave me a collection of allergen solutions, most of which were the first of the kind to be used in England. In the last twenty-three years I have had an extensive experience of the skin tests, which have been applied by various experts but never by myself. The results have been profoundly disappointing, as with two or three exceptions they have never revealed an allergen responsible for a patient's asthma that had not already been recognized by careful cross-examination. On the other hand, on several occasions I have been told that a positive reaction was obtained with a food which the patient rarely or never ate or with the emanation of an animal or a pollen with which he never came into contact, and in other cases no reaction was obtained with an allergen to which the patient was proved to be sensitive.

---

* The opening address in a discussion in the Section for the Study of Disease in Children at the Royal Society of Medicine, Nov. 27, 1942.

Reflex Causes

The respiratory tract is the main reflex source of asthma. When a child with a narrow nasal airway lies down at night the passive congestion of the cavernous tissue of his turbinals may be sufficient to bring them into contact with the irritable mucosa of the septum and thus give rise to reflex bronchial spasm. The narrow airway may be congenital, or the result of an injury or of chronic infection which leads to permanent congestion of the mucous membrane and the development of polypi. Intermittent congestion is also a common reaction to the inhalation of allergens. Suitable treatment, with a minimum of surgery, may prove very beneficial, and no asthmatic child should be allowed to remain a mouth-breather.

In many cases the first attack of asthma in a child is the direct sequel of an acute bronchial infection, and subsequently all or the majority of attacks may follow a cold or bronchitis, to which some asthmatic children are especially liable. The infection may act in two ways. It may lead to a temporary increased permeability of the nasal or bronchial mucous membrane, which allows access to the blood of an effective dose of an allergen, such as that in feathers, with which the child can come into contact at ordinary times with impunity. The extremely irritable condition of the inflamed bronchial mucosa in acute bronchitis may also lead to bronchial spasm by a short or long vagal reflex. There is no evidence that a patient is ever allergic to the toxins of the infecting organism. It is consequently not surprising that by using adequate controls Knott demonstrated that autogenous vaccination has no direct effect on asthma. When, however, asthma is secondary to chronic respiratory tract infections in patients over 35, short courses of prophylactic inoculations in the spring and autumn often appear to reduce the liability to infection and to the resulting asthma.

A distended stomach and a distended rectum may both produce reflex attacks of asthma, which is never caused by alimentary toxaemia. Evacuation of the stomach by vomiting and of the rectum by a well-conditioned defaecation reflex without the use of drugs or enemas gives immediate relief, which could not have happened if the asthma had been the result of alimentary toxaemia—the so-called, but mythical, "asthma toxicosis," about which several monographs have been written.

Psychological Causes

The most common psychological exciting cause in asthma is expectation, the effect of which Bree recognized in his own case as long ago as 1797. An asthmatic who has been accustomed to having attacks in certain places or under certain conditions is very likely to continue to do so when the original allergic or reflex causes have ceased to be operative. Frequent repetitions result in a well-established conditioned reflex. Thus an attack caused by pollen or food during a visit to a certain town may produce reflex asthma conditioned to the town even at a time when neither the pollen nor the food is in season. Certain emotions may also give rise to attacks, as Floyer pointed out 200 years ago. Of these, annoyance—often manifested as outbursts of temper—excitement, and anxiety are the most common. A frequent cause of temper is the strict diet imposed upon a child on account of positive skin reactions to certain foods. It is too much to expect a small boy not to feel resentful on being forbidden to eat a favourite food when he sees his brother and sister and friends enjoying it. It is far better to send him away from home to surroundings in which he can eat everything with impunity than to remain at home, where he comes to regard himself as differing in some strange way from other boys and girls. Laennec told how fright led to an attack in a patient of his when his night-light went out, corresponding with the patient of to-day who becomes severely asthmatic if he breaks his syringe or finds that he has left his adrenaline at home.

The bad influence of the home on many asthmatic children is to a great extent a reflection of their parents' anxiety. It is the psychological rather than the allergic atmosphere from which they need to be removed. Confirmation of this is provided by the frequency with which an attack follows the first visit of his parents to a child who has been moved to new surroundings. Except for encouragement and simple explanatory talks for older children direct psychotherapy is rarely required, but it is always important to teach the parents of asthmatic children the proper attitude they should adopt towards them. The first essential is to hide completely any anxiety they may feel. A spirit of optimism should be instilled into both the patient and his parents, and they should be made to realize that improvement is likely to occur before long and that conditions which have hitherto given rise to asthma may at any time cease to do so. The child should not be pampered, but be encouraged to lead as normal a life as possible. He should be kept in bed for bronchitis but not for asthma. He should be sent to a boarding school at as early an age as possible.

Asthma Treatments

In 1902 a specialist from over-seas, having cured 347 of his 402 asthmatic patients by cauterizing what he regarded as an asthmogenic point on their nasal septa, settled in London. He was at first successful with the 80% of his cases with normal-looking noses, the remaining 20% being the unhappy people with abnormal noses, often in part the result of surgery. Forty years have passed since then, and this method of treatment is almost forgotten, having given place in succession to at least a dozen other specific treatments, each with its 70 or 80% of cures. The inventor of one of these—inoculation with an albumose isolated from the urine—told the secretary of the Asthma Research Council that it was unnecessary to collect any more funds, as the asthma problem had at last been solved! A Leyden professor cured 80% of 800 patients by putting them in air-conditioned rooms, in which cacti were the only plants that could live and in which cut flowers faded within an hour. "The efficient treatment of asthma is impossible," he wrote, "without employing an allergen-proof chamber." I arrived at an Amsterdam hotel the same day as another asthmatic from England entered his clinic. I lost my asthma the same night after a good dinner and a visit to a music-hall, whilst he took several days to lose his in a stuffy but air-conditioned bedroom. A couple of years after the inventor's death the tall chimneys of the allergen-free houses, which had given the distant view of Leyden a unique appearance, had all disappeared.

A few years ago many rooms in England were adapted at considerable cost for a new form of inhalation therapy, which was introduced by an unqualified practitioner and boosted by a film star and a number of medical men. Later the inventor had to leave the country, and so far as I know all the installations are now derelict.

Treatment by specific desensitization has had a more widespread and lasting popularity than any of the earlier forms of specific treatment. Investigations, begun by E. T. Conybeare and Witts (1935) and continued by Boland and Lintott (Boland 1938; Boland and Lintott, 1939) at the Guy's Asthma Clinic, have shown that *improvement occurred in the same percentage of cases treated with injections of normal saline solution as with injections of specific allergens.* In a later series, in which paroxysmal rhinorrhoea was the most prominent symptom, Boland and Lintott found that desensitization with inhalant protein had no greater beneficial effect than normal saline solution given with the same ceremony.

Non-specific protein injections in the form of peptone, tuberculin, sanocrysin, or the patient's own blood gave equally good results in the hands of those who believed in them, no doubt because the suggestive effect is the same whatever the nature of the injection.

With an experience of 2,000 cases spread over a period of forty years James Adam of Glasgow claimed to get excellent results from a special diet combined with nasal treatment. The diet, which he described in great detail in his monographs on asthma (1913, 1939), was one which he believed prevented "toxicosis" and did not depend in any way upon the avoidance of foods to which the patient might be found to be allergic.

Before the war every good Frenchman who suffered from asthma took his annual holiday at Mont Dore, *le providence* *des asthmatiques*, and every good German asthmatic took his at Bad Reichenhall. My own experience at these resorts convinced me that they acted entirely by suggestion. At Mont Dore one drank the water, inhaled its vapour, and, to make doubly sure, had a daily foot-bath in it. My first visit I enjoyed, and it did me good. My second visit I went without my wife and I hated it; it made me worse, but I got quickly well when I joined her in Paris. The psychological atmosphere at Bad Reichenhall was so unpleasant that I did not cease being asthmatic till I left for Pontresina, where I was at once able to walk and climb all day with complete comfort.

All these forms of treatment produce approximately the same percentage of temporary "cures." They are so diverse in nature that the only thing they have in common is the faith their exponents have in them, a faith which is transferred by suggestion to the patient with sufficient strength to be successful in about 75% of cases. Unfortunately the asthma diathesis remains unaffected, so that recurrence is just as frequent as after spontaneous remissions.

Treatment

The Asthmatic Thorax and Expiratory Exercises.—In an attack of asthma the obstruction caused by the spasm of the bronchioles is diminished by the rise in the negative pressure in the thorax caused by the forced inspiration and increased during the forced expiration by the conversion of the negative into a positive pressure. This explains why asthma differs from all other forms of dyspnoea in being mainly expiratory. The lungs at once become distended to the utmost, and only very limited deflation is possible. Swift relates how a farmer of his friend Anthony Henley, "suffering of an asthma, said, 'Well, if I can get this Breath once *out*, I'll take care it shall never get in again.'" If the attacks are frequently repeated or prolonged the thoracic muscles assume a new postural tone, so that even when the attack has passed the lungs remain over-distended and the characteristic big chest, hunched shoulders, and wide epigastric angle of the chronic asthmatic persist. The respiratory excursion is much reduced and the child is unable to take exercise without dyspnoea. This condition is often mistaken for emphysema, but in contrast with true emphysema it can be rapidly and completely cured by expiratory exercises, an excellent illustrated description of which has been edited by Dr. Livingstone for the Asthma Research Council. These exercises restore the normal postural tone of the thoracic muscles, so that the chest resumes its natural shape and the lungs their normal size, the respiratory excursion returns to normal, and the child is able to take vigorous exercise without distress. So long as any tendency to asthma persists, simple expiratory exercises should be carried out every morning and evening unless an attack is actually present, and any postural errors, especially habitual shrugging of the shoulders, should be corrected.

Exercise, Clothing, and Baths.—Expiratory exercises should not be regarded as a substitute for walking and open-air games but as a form of training. Nothing is more undesirable than prohibiting games. An asthmatic child should be taught to regard his asthma as an inconvenience and not a disease. It is almost always possible to find a school where he is free enough from attacks to be able to join in every kind of sport. Swimming is particularly beneficial. In peacetime, whenever possible, the Christmas holidays should be devoted to winter sports, and especially ski-ing. If exercise is found to cause shortness of breath, this can often be prevented by taking a small dose of ephedrine or theophylline half an hour earlier. The modern reforms in children's clothing are most welcome, and no boy or girl with an asthmatic tendency should be sent to a school where the ancient and unhealthy fashions are retained. Asthmatic children should be encouraged to have a cold bath every morning all the year round or at least a cold douche after a hot bath of very short duration. Bed is the worst place for an asthmatic in the daytime unless bronchitis is present, and even after a disturbed night it is best to have a cold bath and get up for breakfast, if necessary after a preliminary dose of ephedrine or theophylline.

The Allergic Factor.—In many cases it is possible to discover by a carefully taken history one or more allergens to which a patient is sensitive. These should be avoided as completely as possible, and it is probably always wise to substitute kapok for feather pillows and to use face-powders which do not contain orris-root. I regard an attempt at specific desensitization as justifiable only when a patient is sensitive to an allergen which it is impossible for him to avoid without grave inconvenience, and even then it is doubtful whether any good effect it may appear to have is not the result of suggestion. It is essential that this allergen should be used alone, even if, as is commonly the case, the patient is also sensitive to others. If it is only one ingredient of one of the pernicious mixed brews on the market it is impossible to increase the dose of the specific allergen sufficiently without causing an excessive reaction from the dust extract which they contain and which is poisonous for everybody.

Iodide.—Many asthmatic attacks end with the expectoration of tenacious mucus, but coughing always aggravates the dyspnoea. A small dose of iodide taken at night or night and morning makes the sputum more watery and much easier to expel. The patient should be taught to control his desire to cough; he will then be able to expectorate the mucus a few minutes later quietly and without effort. Stramonium is often prescribed with iodide, but the harm it does by counteracting the good effect of the iodide by drying the secretion and by upsetting the digestion more than outweighs any slight benefit which might follow its feeble antispasmodic action.

Caffeine and Theophylline.—Strong coffee has long been a popular remedy for mild asthmatic attacks, and for nearly forty years I have known how useful caffeine is in helping asthmatic patients to take exercise which would otherwise have been impossible. I have recently found theophylline monoethanolamine still more effective, and I regard its introduction by Lamson and Bacon (1941) of Los Angeles as one of the greatest boons to chronic asthmatics since the discovery of the effect of adrenaline in 1910 by Brian Melland of Bowdon. It is supplied in capsules under the trade name of theamin. The usual dose for adults is one or two 3-grain capsules, but in children 1 or 2 gr. is often sufficient. It is more effective than ephedrine and less likely to cause unpleasant symptoms. It often prevents the development of dyspnoea if taken before exercise, and prevents nocturnal attacks if taken on going to bed. Mild attacks in the daytime can be aborted if it is taken early enough, but, like ephedrine, it is useless for attacks of any severity.

Adrenaline.—With a good "adrenaline technique" it is always possible for a patient, however frequent and severe his attacks, to control them sufficiently to enable him to lead a life of moderate activity and to avoid becoming a hypochondriacal invalid. In exceptionally severe cases in adults it may even be necessary to give a dozen or more injections a day for long periods. But the patient is still able to carry on his business or profession, and if his technique is good enough he can continue to appear before the world as a fit man. I once taught the adrenaline technique to a surgeon who had decided to retire on account of severe asthma. The new regime made it possible for him to remain in full activity for nearly twenty years, when he died from an acute abdominal disorder. When old enough, the patient should be taught to inject the adrenaline himself at the first sign that an attack is developing: 1 to 4 minims is generally sufficient to abort it, though 5 minims or more would have been required to arrest it if he had waited for somebody to give him the injection when it was fully developed. The small dose produces none of the unpleasant symptoms often caused by large doses injected too rapidly; it leads to no rise of pulse rate or blood pressure. The frequency of injection is immaterial, as there is no cumulative action, but it is of course most important that the patient should not get into the habit of injecting adrenaline when it is not really required, or for mild dyspnoea in the daytime which could be controlled by ephedrine or theophylline. No asthmatic need ever have a bad night; he should sleep eight or nine hours even if he wakes four or five times with asthma, as prompt treatment will send him to sleep within five minutes.

The rare condition of status asthmaticus, in which severe asthma continues uninterruptedly for days or weeks and may end in fatal exhaustion, can almost invariably be arrested by the method of continuous adrenaline injection, which I introduced 18 years ago. The needle is kept in position, and after an initial injection of a dose which is known to cause no unpleasant symptoms, 1 minim is injected every 15, 30, or 60 seconds, according to the patient's reaction, the rate being adjusted so as to cause no unpleasant symptoms and no acceleration of the pulse. The injections are continued, if necessary, even for half an hour or more until relief occurs.

Conclusion

It may perhaps be thought that I have been too pessimistic about the treatment of asthma. But though I am no believer in "asthma cures," and though I regard most of the popular treatment to-day, like that of ten, twenty, and thirty years ago, as nothing more than gross suggestion, yet I know that every asthmatic can derive much benefit from good advice. He can be taught a way of life and, among other things, how to avoid the exciting causes of his particular brand of asthma, how to control attacks which he is unable to prevent, and above all how to be happy in spite of the bad luck of having been born with the asthma diathesis.

PSYCHOLOGICAL FACTORS IN ASTHMA*

BY

C. H. ROGERSON, M.D.

Medical Director, Cassel Hospital for Functional Nervous Disorders

For some years, and especially at Guy's Hospital between 1933 and 1937, it was my privilege to study in considerable detail a series of children suffering from asthma. Many of these cases have presented in addition other manifestations of what has been termed the asthma–eczema prurigo complex. I have not been able to satisfy myself that any significant distinction could be made between children suffering from asthma alone and those showing skin symptoms; but to avoid any misapprehension I would like to make it clear that my cases included a rather high proportion of sufferers from eczema prurigo—many of them, indeed, came originally from the skin department.

Upon the basis of my work I wish to make certain observations concerning the causation and treatment of asthma. It has been a common experience of mine to find that in a case in which psychological factors were obviously prominent all physical measures had been exhausted before the patient was handed over to the psychiatrist as a last resort. No psychiatrist who had any experience of asthma would claim that physical treatment should be laid aside in favour of psychological treatment. He would, however, in every case feel strongly that psychological treatment should supplement physical treatment at the time when the latter treatment was being given and not as an afterthought. In the great majority of cases the psychological treatment ought not to be given by the psychiatrist at all, but by the physician in charge of the case, and should consist of an assessment of the total situation in which the illness is occurring, having regard to certain principles which I propose to lay down, followed by an attempt to bring correction to bear on those points where it is needed. In a minority of cases technical psychotherapy is required, and should be given along with the physical treatment.

Influence of the Parental Attitude

I will deal first with the psychological factors in the causation of asthma. There is in this disease among children one observation which we must all have made, and which stands out clearly in case after case—namely, that there is an unusual quality in the relations between the child and one or both of his parents. I shall here quote from observations of my own made in 1934 upon one of the earlier cases I was able to study intensively.

The patient, a boy aged 7, was referred to me because he suffered from the fully developed asthma–eczema prurigo complex. My notes contain the following description: "The child came into the out-patient department clinging to his mother and afraid to leave her side. He was pale and thin, with bright eyes and an anxious countenance. During the course of the interview he wheezed continually and scratched himself surreptitiously. When now and again his mother observed him in this latter practice, she appeared greatly distressed and stopped him momentarily. After numerous fruitless attempts to make him leave off she broke down and wept in a hopeless fashion. There was an air of tension in all her dealings with him, as if she was expecting that at any moment something unforeseen but altogether terrifying might happen to him. The child reflected perfectly the maternal over-anxiety. He described his symptoms in an adult manner, speaking in terms of irritation of his skin and a tightness in his chest."

It is merely necessary for me to add that he was an only son of good and conscientious parents, who regarded him as better than the other children in the neighbourhood, with whom he was not allowed to play.

This case must be typical of hundreds, and one's first reaction is to blame the mother for her over-protection and over-anxiety, and to demand that the child be given greater freedom and be allowed to play with other children. The results of such action often seem to justify the belief that parental over-anxiety is the chief psychological factor in the production of symptoms. In this particular case the line of treatment I have described was followed, in conjunction, of course, with such physical treatment as was deemed necessary. The result was remarkable: the timid over-anxious child became bold and aggressive; his asthma and his skin condition both died away.

Such a formulation as this, however, necessarily leaves one dissatisfied. We know that not every over-protected child develops asthma. Is the special parental attitude in these cases, then, of no particular significance—no more, in fact, than one would expect to observe in any sickly child? Or is there, on the contrary, some fundamental connecting link between the personality of the asthmatic child and the anxiety of his parents? These are questions to which I believe I can give a definite answer which also goes a long way towards correlating the psychological side of the asthma problem with the various physical facts known about it. For the sake of clarity I shall give my answer and then proceed to adduce the facts upon which it is based.

The Asthmatic Personality

In my experience the asthmatic child tends to be of a special personality type characterized in its purest form by the following features: (1) he has an intelligence much above the average; (2) he is irritable and aggressive, quick to respond; (3) he is over-anxious, insecure, un-selfconfident. As a result of his insecurity he often appears at first sight repressed and submissive, but even then there is generally an air of subdued tension about him, and, given an opportunity for freer and more confident self-expression, he becomes aggressive and domineering. He is, in fact, the type of child who makes more demands upon his parents, particularly his mother, than almost any other. He is an intelligent individual who twists her round his finger, aggressive enough to get his own way and anxious enough to demand her continual attention. Again and again I have seen children who subsequently developed asthma showing in their earlier years all these characteristics and developing with their distracted parents a relation exactly like that seen in the case of the full-blown asthmatic. To fulfil their own personality needs they both dominate and demand protection from their parents. The fulfilment of these exaggerated needs, however, leads them, as we all know, ultimately into a state of frustration which they cannot either tolerate or get away from; thus the typical relationship development—aided, of course, in many cases by maternal over-anxiety.

Now for the facts upon which I base my assertions concerning the asthmatic personality.

Intelligence.—I have records of the measurement of intelligence by trained psychologists of more than 50 of these children who attended the department of psychological medicine at Guy's Hospital. The average intelligence quotient was 108.8, as contrasted with an average of 90 for a comparable sample of the population attending the same department suffering from other conditions. This very great discrepancy is of course statistically significant and indicates a marked intellectual superiority of the asthmatic children over the general population. I do not assert that every asthmatic child is a genius, but the tendency towards high intelligence is very important. (I may add that I have never met with asthma in a mentally defective child. Others may have had this experience.)

---

* A paper read on Nov. 27, 1942, at a meeting of the Section for the Study of Disease in Children, Royal Society of Medicine.

Other Personality Features.—Facts concerning personality apart from intelligence are very much harder to quote or put forward convincingly. I used two methods with a group of 30 of these children. First, I wrote down in full the description given by the parents in response to the question "What type of child is this?" Secondly, I arranged for an independent trained observer to watch a series of children, including these asthmatics, in a playroom and to record her impressions. The results were as follows: 23 out of 30 patients were described by parents as nervous; 22 as restless, active, excitable; 19 as irritable, aggressive, domineering; 21 as over-anxious, un-selfconfident, afraid. From a corresponding group of children referred to the department of psychological medicine for neurotic difficulties or behaviour disorders it was found that 6 were described as restless and excitable, 4 as aggressive and domineering, and 6 as over-anxious and afraid. These observations were fully confirmed by more detailed studies in children's play, which it would be inappropriate to quote here at length.

As already stated, these same personality features were so often observed by reliable witnesses before the development of the asthma that I am not prepared to believe them secondary to that condition. Indeed, the intelligence quotient stands out as a fact which cannot be explained away in any such fashion.

What is the Meaning of this Personality Type?

I believe this question has a simple answer. On the physical side one of the fundamental facts concerning the asthma-eczema prurigo subject is his abnormal sensitiveness and irritability. His skin, his mucous membranes, his smooth muscle, are all apt to react violently and excessively. I consider that his personality is nothing more than a psychological expression of those same traits. He is quick to react and highly irritable, and it is interesting that the word "irritable" should be used alike of a state of the mind and a state of the skin. He is literally more highly strung than his more, or possibly less, fortunate brethren.

The facts which the psychiatrist observes are corollaries of the facts which the physician studies. They are, to paraphrase Sherrington, two ways of one mind and body, and until we are prepared to accept them as such and to treat them simultaneously we shall not be doing all that is possible for the alleviation of the condition.

Relation between Psychological Difficulties and Asthma

Finally, a few observations concerning the relation between psychological difficulties which I have indicated and the actual phenomenon of an asthma attack. There are certain broad ways in which psychological conflict may be converted into physical symptoms:

1. The symptom may be symbolic of the nature of the conflict, as when, for example, a feeling of choking follows thoughts of drowning.
2. The symptom may be a sign but not a symbol of the nature of the conflict. This distinction, which is perhaps more familiar to philosophers than to physicians, is here very important. For example, palpitation and sweating may be a sign of anxiety; they are not, however, under most circumstances symbolic of the nature of the anxiety.
3. The symptom may be the result of a conditioned reflex.
4. The symptom may be teleologically determined—i.e., as a means of avoiding a difficulty or gaining an end.

I suppose that all these relations may exist in the case of asthma. Trousseau gave us a classic example of the conditioned reflex. Psycho-analytical literature affords us examples of the symbolic asthma attack—for instance, when the asthma attack is traced to an early repressed fear of suffocation. Such examples have, I fear, not always been very convincing. The teleological factor may play a part—some asthmatics certainly seem able to turn on an attack at a convenient moment—but it can seldom be of primary importance. In both these relations, the symbolic and the teleological, it is of course important to distinguish between true asthma and hysterical hyperpnoea. I doubt whether this distinction has always been drawn with sufficient care.

In the vast majority of cases the asthma attack is, I am sure, a sign of the conflict, its general resultant, in the same way that palpitations are the general result of fear. The important factor that in nearly every case appears to be the connecting link between the psychological conflict and the physical symptom is tension. From the psychological point of view the asthmatic stands tension very badly. When pent up, thwarted, or frustrated he develops asthma upon the slightest provocation. When free and relaxed he is able to stand far more harmful stimuli without developing an attack.

In describing the reaction between the asthmatic child and his parents I mentioned that he secured his immediate needs (i.e., domination of his parents and their constant attention) at the expense of his ultimate needs—that is, freedom of self-expression. The situation which he helps his parents to create is one in which tension is specially engendered. Of course parental difficulties are not the only problems of the asthmatic which create tension. In adults especially, failure of plans, quarrels, and frustrations of all kinds may give rise to the attack. One of the worst offenders is the asthma itself, which interferes with the self-expression of the sufferer and so creates a vicious circle in which the more severe the asthma the greater the frustration. This seems to be the reason why so many patients have found that it was necessary for them to continue their normal lives at all costs, regardless of asthma attacks, otherwise they became much worse. With increased tension comes also increased anxiety, and therefore increased feeling of insecurity. The improvement that follows some line of physical treatment confidently adopted may often be attributed to the feeling of confidence which it produces.

The psychological factors I have described are capable by themselves of producing an attack. Often, however, they provide a background, augmenting and reinforcing the more obvious physical features. Trousseau gives an example of this when he quotes his own experience to the effect that the combination of stable dust and rage at a cheating coachman produced one of the worst asthma attacks of his lifetime. There are more subtle examples too. I have on at least three occasions observed children who were definitely sensitized to one or other of the common forms of foodstuff and who developed asthma in their home surroundings on exposure to these foods and yet ate them with impunity in the freedom of a convalescent home.

I would say, therefore, that one of the most important but least appreciated roles of the psychological factor in asthma is to render the organism more sensitive to the operation of the physical factors, whatever they may be, which produce the attack.

Conclusion

Having formulated these general principles the treatment would appear clear enough. In many cases the person best able to modify and direct the child's personality development is the child's own parent, and the physician's role should be that of guide to the parents, and often their supporter, in their efforts to follow his instructions. He should bear in mind that the relationship which he observes may not be entirely the fault of the parents, who are often not such fools as they may appear. Where the child's personality is very difficult psychiatric help may be required in modification, but the psychological problem is usually best dealt with by the physician who is looking after the case and who is in control of all the remedial agents. I do not believe there is any doubt that psychological treatment of the kind I have described can play a very important part in moderating the symptoms.

Perhaps I may fittingly conclude with the remark of the mother of the child whose case I described at the beginning, who said after a period of guidance: "He used always to cling to me and wheeze so dreadfully; but now I have made him stand on his own bottom, and he does not have asthma any more."

Much of the work upon which these observations are based was carried out at Guy's Hospital under the direction of Dr. R. D. Gillespie and with the aid of the Rockefeller Foundation. I am greatly indebted to both.

THE TREATMENT OF BURNS

BY

J. M. BARNES, M.B., B.Chir.
Nuffield Research Fellow in Surgery, Oxford

This paper describes the methods of treatment used for cases of burns admitted to the Accident Service of the Radcliffe Infirmary. On account of its importance the treatment of burns of the hands is given in some detail.

Principles of Treatment

Burns are wounds with special characteristics. The treatment of each should be governed by the same principles, which may be defined as follows:

1. *Time.*—The injury must be treated at the earliest opportunity.

2. *Cleaning.*—The lesion and its surroundings must be thoroughly cleaned without further injury to the tissues.

3. *Excision of Dead Tissues.*—This is the most important step in the successful treatment of all wounds. Unfortunately the size and situation of burns, together with the difficulty of distinguishing dead from living tissue, render the complete excision of all devitalized tissue impossible in the majority of cases.

4. *Drainage.*—No provision for drainage need be made. The aim of treatment is to keep the burned area as dry as possible. Natural drainage may be hindered by the superimposition of an impermeable coagulum, such as that produced by tannic acid and similar agents.

5. *Rest.*—Damage to the growing tissues partaking in the repair of the lesion is avoided by keeping the part at rest. Rest is the most effective means of abolishing pain and the accompanying muscular spasm. Infrequent dressings minimize injury to tissues growing on the surface.

6. *Prevention of Oedema.*—Oedema should be prevented by the application of firm pressure (Siler and Reid, 1942) or, when a limb is involved, by elevation of the limb. Fluid leaving the damaged capillaries round a wound forms the exudate which escapes from the raw surface, and the growth of organisms is favoured by the excessive moisture. At the same time, fluid escaping into the tissues is removed by the lymph stream. Therefore, movement of an oedematous part carries with it a greater risk of sweeping bacteria and their toxins into the general circulation (Barnes and Trueta, 1941).

7. *Replacement of Lost Skin.*—Where the full thickness of the skin has been destroyed it should be replaced at the earliest opportunity by means of skin grafts.

Technique of Treatment

On admission of the patient to hospital a rapid examination of the burns is carried out. Morphine (1/4 gr. for an adult) is given, and the patient made comfortable in bed. When the burns exceed 10 to 20% of the body surface, and shock is likely to develop, a transfusion of human serum is immediately started. Serum is preferred to plasma because of its higher protein content. The pulse rate and blood pressure are recorded at intervals of 15 to 30 minutes, and the haemoglobin estimated. In the initial stages no attempt is made to calculate the total fluid requirements on the basis of a single determination of the haemoglobin. Such calculations are misleading, because fluid continues to escape from the blood during the first 48 hours. Thus the haemoconcentration may actually increase while fluid is being administered (Fig. 1). The rate and amount of the transfusion are controlled by the blood pressure. The cessation of transudation from the capillaries, and of the need for transfusion, is shown by the return of the haemoglobin to approximately normal levels.

As soon as the patient is under the influence of morphine he is transferred to the operating theatre. Originally a general anaesthetic was administered in order to clean the burns, but it has been found possible to carry this out, both in adults and in small children, under the influence of morphine alone. Special gentleness is necessary when cleaning the palms of the hands and the edges of the burn, because these are the most sensitive parts. The burns are cleaned with soap and water, or with some more powerful antiseptic detergent—e.g., cetyl-trimethyl-ammonium-bromide (C.T.A.B.) (Barnes, 1942). In order to ascertain the percentage of cases that were infected before admission to hospital bacteriological examination was carried out on swabs from the untreated surface of burns admitted within 48 hours of the accident. In an unselected group of 52 major and minor burns pathogenic organisms were isolated on seven occasions (haemolytic streptococci, 2; *Staphylococcus aureus*, 5). It is clear, therefore, that the majority of cases that become infected do so only after admission to hospital. This is due to exposure to infection from the nose, throat, and, in particular, hands of nurses and doctors, and possibly from infected bedclothes.

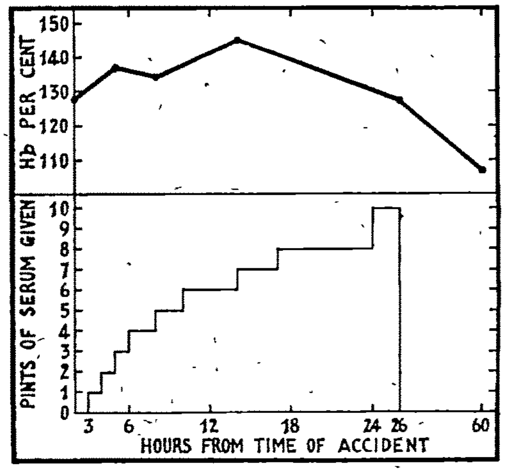

FIG. 1.—Records from a severe case of burns, showing rise of value of haemoglobin during course of serum transfusion. The patient was a man aged 32 with extensive burns of body and arms.

During the cleaning all loose epidermis is removed, and blisters are either excised or punctured and pressed down on the raw surface. A final washing with soap and water is given, and the surface lightly dried. A single layer of fine-mesh good-quality bandage, which may be either dry or impregnated with vaseline, is applied. On the whole I prefer the dry bandage.

For the limbs, including the hands, complete immobilization is secured by enclosing them in plaster-of-Paris casts applied directly over the gauze. The hand is placed in the "position of function"—i.e., slight dorsiflexion of the wrist, 60 degrees flexion of the metacarpo-phalangeal joints, 45 degrees flexion of the interphalangeal joints, and with the thumb opposed to the index finger. In such a position maximal relaxation of the long muscles of the fingers is obtained. If the burn is deep, or if it extends above the level of the wrist, the elbow is immobilized. The olecranon and epicondyles are padded, and the joint is fixed in a slightly flexed position (120 degrees), with the forearm semi-pronated. A thick pad of wool is placed round the arm at the upper level of the cast in order to fill the gap that will otherwise inevitably appear between the limb and the plaster during the first few days. The cast is made with a long slab of plaster laid over the back of the forearm, moulded over the fingers, and carried up the front of the forearm. The cast is completed by one or two plaster bandages, and a small loop is made by which it may be suspended (Fig. 2).

For burns of the trunk a thick dressing of wool and gauze is firmly applied with crêpe bandages. The dressings should extend well beyond the margins of the burn, and many bandages should be used to prevent gaps appearing in the dressings as a result of movements of the patient in bed. When a limb is extensively burnt, thoraco-brachial and hip spica casts are used. On the other hand, a burn of the trunk alone is not enclosed in plaster, because of the lack of complete immobilization within the casts.

Subsequent Treatment

When the burn is extensive continuous records of blood pressure and haemoglobin are made for the first 48 hours or so. The urinary output is measured: a return of the normal output is a good prognostic sign. Dressings are kept as dry as possible by exposure to the warm air of the room. During the first few days they become soaked with exudate from the dependent parts, and thus provide an avenue for infection which may reach the burn. Large plaster casts must be dried under a heat cradle and similar precautions be taken to keep them dry. When soakage does occur it is inadvisable to change the dressings or casts, for this would still further increase the risks of infection. The exudate dries after the second day, and by no means every such case becomes infected. Among the cases I treated there was a high incidence of infection with *Ps. pyocyanea.* The appearance of the characteristic green pus indicated that in the majority of these cases infection started from the edges of the dressings, and presumably came from the bedding.

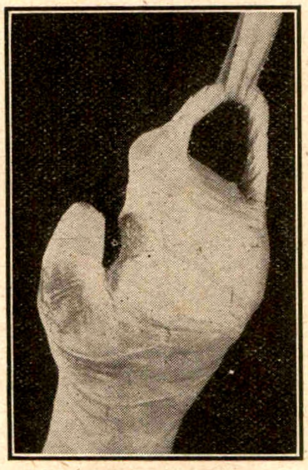

Fig. 2.—Photograph showing complete enclosure of a burnt hand in plaster. Note loop for suspension of cast.

Management of the Plaster Casts

When a fresh burn of the hand and forearm is enclosed in plaster it is essential that the limb should be adequately elevated. Failure to do so is followed by swelling and intolerable pain. The hand must always lie above the level of the elbow and the elbow above the shoulder. It is particularly important to watch the position of the elbow when a patient sits up in bed during the first few days. When these precautions were observed it was never found to be necessary to interfere with casts applied as early as three hours after the accident.

When the plaster has dried the cast becomes warm. This warmth over the region of the finger-tips is an indication of a satisfactory circulation beneath the plaster. Movement of the fingers within the cast can usually be detected after 24 to 48 hours. When vaselined gauze is used as a dressing the vaseline soaks through the plaster during the first 24 hours. Other than this there is no exudate unless the burn is infected. It is important to use an absorbent type of plaster (home-made bandages) so that any exudate formed may readily make its way to the outer surface. Elevation should be maintained for two days in the case of superficial burns, and for periods up to 10 days when the burn is deep or infected. Elevation considerably reduces the exudate from an infected burn. If elevation is maintained for several days the elbows may become sore. This may be relieved by abducting or adducting the shoulder in order to shift the pressure points.

Change of Dressings

The initial dressing is left in place for 10 to 21 days. Superficial burns are usually healed at the end of this time (Fig. 3). For deeper burns the dressings are changed in order to remove any sloughs that have become loose. When casts are applied to burns of the hands that are seen late and are already oedematous, they will become loose within a few days. It may then be necessary to change the cast earlier, but when there is a serious local infection it may be wiser to delay the change in order to avoid possible systemic reactions as a result of the manipulations (Fig. 4).

Dressings are changed in the operating theatre with the usual aseptic precautions of a surgical procedure. In order to avoid injury to the fingers plaster casts are removed with a knife rather than with plaster shears. The dressings are carefully removed, and those that are dry and adherent to the surface are not disturbed. The raw surface is cleaned with soap and water. Loose sloughs are cut away, taking care to avoid injuring living tissue beneath. At each change of plaster for a burn of the hand the patient is encouraged to put the wrist and fingers through a full range of movements. A fresh dry dressing and another cast are applied if the burn is not healed. After the first change, dressings are renewed at intervals of 7 to 10 days until either healing is complete or all dead tissue has separated and the surface is ready to receive a graft. Grafting can be undertaken with every prospect of success 3 to 6 weeks after the time of injury.

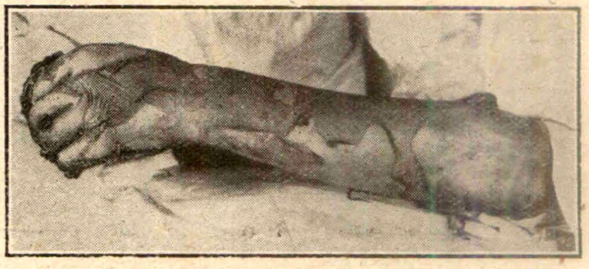

Fig. 3.—Petrol burn of hand and forearm cleaned with soap and water, put into plaster cast, and left undisturbed for 3 weeks. Healing complete on removal of cast. Full function returned within 24 hours.

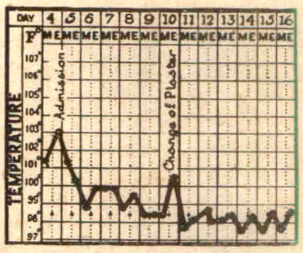

Fig. 4.—Temperature chart of man aged 42 admitted with septic tanned burns of both hands and arms. Casts applied to both arms. 7 days later plaster casts were changed because they were very loose. Note rise of temperature, which was accompanied by a rigor.

Skin Grafting*

In the majority of cases thick split-skin grafts cut with the Padgett dermatome were used. No attempt was made to clean the raw surface by means of frequent wet dressings before grafting. Dressings or plaster casts that had not been changed for periods up to 14 days were removed at the beginning of the operation, and the surface cleaned with soap and water or C.T.A.B. immediately before applying the grafts. Although the number so treated was small, it is worth recording that 10 consecutive cases were successfully grafted in the presence of infection with *Ps. pyocyanea.* A firm dressing was applied over the grafts, and a plaster cast was sometimes added. Limbs were elevated to control exudate from the surface. The grafts were not inspected for 10 days.

Functional Results

In a series of 20 hands immobilized in plaster casts for 3 to 5 weeks permanent stiffness was never seen (Figs. 5 and 6). It must be stated that in only one case was the burn severe enough to lead to exposure of the extensor tendons after the separation of the slough. The fingers recover their mobility within a few days of the removal of the cast if active exercises are encouraged. The newly healed skin may feel tight, but this can be relieved by rubbing in lanolin, as recommended by Wakeley (1942). The hand and wrist may temporarily feel weak as a result of the immobilization of the muscles.

---

* The operations in these cases were performed by Dr. J. M. Converse of the American Hospital in Britain.

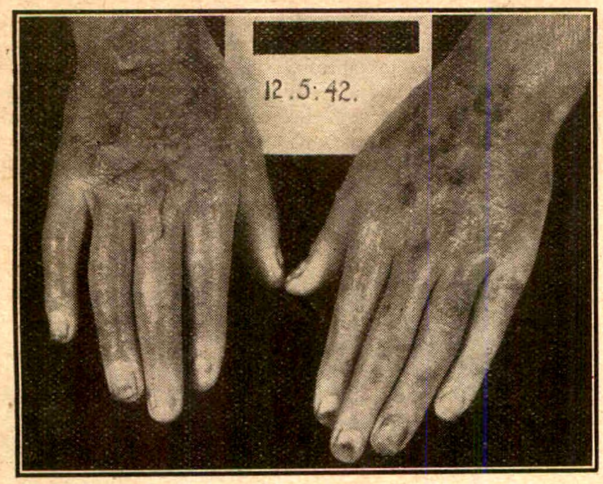

FIG. 5.—Burns of hands of man aged 32 immobilized for 3 weeks; grafted and immobilized for 10 days.

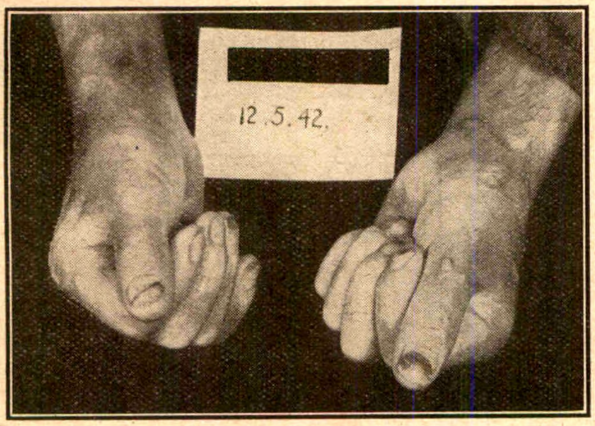

FIG. 6.—Same patient as Fig. 5. Movements 8 weeks after accident.

Discussion

It has been found possible to treat burns by methods similar to those successfully applied to the treatment of other wounds. Burns are particularly liable to become infected, on account both of their size and of the impossibility of removing dead tissue. The incidence of infection can be reduced only by exposing the lesions as infrequently as possible. In a busy general hospital dressings can be carried out with proper aseptic precautions only if they are done at long intervals, thus permitting time and care to be taken over them. Where infection does take place systemic disturbances resulting from it may be controlled by immobilization of the affected region. The benefits to be derived from the immobilization of a series of infected burns have been described by Roulston (1941). Immobilization of the hand does not necessarily lead to stiffness, provided care is taken to place the fingers in a good position. Nevertheless, it would be unwise to continue such immobilization for periods exceeding 4 to 6 weeks.

It is sometimes stated that part of the treatment in the later stages of a deep burn should include the cleaning of the raw areas by means of frequent wet dressings before applying skin grafts. It seems doubtful whether a case so treated, with all the risks of cross-infection attendant on the frequent changes of dressings, fares any better than one given a single cleaning just before laying on the grafts. The mere presence of bacteria upon the surface of the wound is no indication as to the possibilities of success with skin grafts.

When a large number of cases have to be dealt with simultaneously there is a great advantage in being spared the necessity for the frequent changing of dressings in all the cases. A case of extensive burns is in need of careful and continuous nursing during the first few days. Such attention is the more easily given when there is no need to interfere with the local lesion.

Summary

The principles which govern the treatment of burns as wounds are outlined.

A simple technique of treatment, which includes the use of plaster-of-Paris casts for burns of the hand and forearm, is described. If plaster is applied, elevation of the limb is essential, to prevent oedema, and the hand must be placed in the correct "position of function."

The value of immobilization, infrequent dressing, and the prevention of oedema is pointed out.

Burnt hands do not become stiff merely as a result of immobilization, provided that this is carried out correctly for a limited period.

In spite of the presence of infection with *Ps. pyocyanea*, skin grafts will "take" on granulating burns that are dressed infrequently.

I wish to thank Dr. R. L. Vollum for undertaking the bacteriological investigations, Miss M. H. H. Shaw and Mr. H. Axtall for doing the photographic work. Thanks are also due to the Medical Research Council, who provided a grant for technical assistance.

SULPHAGUANIDINE IN NEONATAL EPIDEMIC GASTRO-ENTERITIS

BY

J. L. HENDERSON,* M.D., F.R.C.P.Ed.
Assistant Paediatrician, Simpson Memorial Maternity Hospital, Edinburgh

Since the virtues of sulphaguanidine in the treatment of alimentary infections were discovered by Marshall and his colleagues (1940, 1941) this sulphonamide compound has won general recognition as the most effective drug hitherto employed in the treatment of a variety of intestinal infections. It has greatly lessened the severity of the symptoms and the duration of illness in the various types of dysentery, and has been very successful in infective gastro-enteritis in infancy and childhood. The principal object of this paper is to record the excellent results achieved with this drug in epidemic gastro-enteritis in the newborn, the most lethal of the commoner neonatal infections.

Epidemiology of Neonatal Gastro-enteritis

Outbreaks of infective gastro-enteritis occur periodically in all maternity hospitals in which opportunities for cross-infection among the infants arise owing to imperfect architectural and nursing arrangements. In all epidemics the vast majority of affected infants are bottle-fed. The publicity given to the prevalence of the disease in the maternity hospitals in New York City by Rice and his collaborators (1937) has focused attention on the appalling waste of infant life in maternity hospitals from this preventable alimentary infection. These workers reported 505 cases of epidemic diarrhoea in 11 maternity hospitals in New York in the 2½-year period July, 1934, to Dec., 1936, the incidence being the very high one of 14%. The earlier literature contains surprisingly few references to such a common disease. The paper based on the largest series of cases, and the only one of note emanating from this country, was published from this hospital in 1936 by Craig. The impetus given to the study of the disease by Rice *et al.* has accounted for the appearance of numerous publications in the U.S.A. (Abramson and Frant, 1938) and this country (Ormiston, 1941; Crowley *et al.*, 1941) in the last few years. These have shown that few maternity hospitals are exempt from periodic epidemics of neonatal gastro-enteritis. The complacent attitude towards this grave infection is attributable to the long intervals which usually occur between successive outbreaks. The causal bacterium or virus still eludes identification. Some believe, however, that normal inhabitants of the bowel may cause the disease by assuming pathogenic properties, as in epidemic gastro-enteritis in lambs. Outbreaks have been attributed to *B. proteus vulgaris*, *B. coli mutabile*, *B. lactis aerogenes*, and other commensals. Special bacteriological assistance has been given in many of the cases in this series, and no organisms of the enteric or dysenteric groups or any other pathogens have ever been isolated. Rice *et al.* and others, particularly in the U.S.A., believe that this disease is confined to the first month of life, but it may be that feeble resistance to infection in the early weeks rather than a distinctive aetiology accounts for the more severe features of gastro-enteritis in the newborn.

---

* Holder of a Crichton Research Scholarship, University of Edinburgh.

Incidence and Mortality Rate

Six epidemics and a few sporadic cases, comprising a total of 102 infants, with gastro-enteritis, have occurred in the Simpson Maternity Hospital, Edinburgh, during the three years 1940-2. For some unaccountable reason there were more epidemics and a higher incidence of the disease during this period than for many years. The incidence was approximately 1.5%. There were 50 mature and 52 premature infants, the incidence in premature infants thus being very much higher than in mature infants. Universal bottle-feeding is the chief reason for the greater incidence in premature infants. The nurseries in this hospital are visited daily by an experienced paediatric staff, and a clinical chart and a record of each infant are kept. A series of uniform observations has thus been made, and it is unlikely that more than a few very mild cases have been overlooked. Cases of gastro-enteritis complicating thrush infection of the upper alimentary tract have been carefully excluded. A post-mortem examination was made by Dr. Agnes Macgregor in all of the 58 fatal cases. Fig. 1 shows the mortality rate in each of the three years, 1942 being divided into the period before the introduction of sulphaguanidine therapy and the period after its commencement. The dramatic fall in the mortality rate in 1942 can be attributed almost entirely to the introduction of this drug. The greatly improved results did not justify the use of controls. The accompanying table shows the relation of the mortality to the maturity in treated and untreated infants.

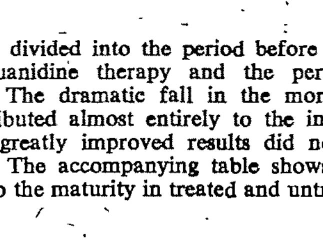

FIG. 1.—Mortality rate in gastro-enteritis before and after the introduction of sulphaguanidine.

Table showing Relation of Mortality to Maturity in Infants Treated with Sulphaguanidine and those Untreated

	Treated		Untreated	
	No.	Mortality	No.	Mortality
Mature infants—over 5½ lb. ..	11	0	39	69%
Premature infants:				
(a) 5½–4 lb., incl.	11	0	19	84%
(b) Under 4 lb.	8	38%	14	86%

Clinical Features

The first signs of gastro-enteritis usually appear after the first week of life, but they occasionally develop earlier. A sudden failure of appetite is the first sign of illness. Diminished vitality, a tired sickly appearance, and pallor follow within a few hours. Diarrhoea as a rule develops within a few hours of the onset, but may be delayed for 24 hours. The stools are watery in most cases. They are usually yellow, but may be greenish, and mucus is occasionally present. Blood sometimes appears in severe cases. The stools frequently exceed 10 a day and are sometimes uncountable. Signs of dehydration usually appear by the second day, and rapidly become severe in the absence of appropriate treatment. Approximation and overlapping of the cranial bones with a reduction in the size of the anterior fontanelle are often earlier signs of dehydration than a pinched facies. The weight course shows a sudden reversal, and the loss amounts to several ounces daily. Fever is an inconstant feature, but there is often a moderate degree either at the outset or at a later stage. Vomiting is absent in many cases; it tends to be a much more pronounced feature in some epidemics than in others, and the diarrhoea is sometimes milder when the vomiting is severe, suggesting a predominantly upper alimentary infection. Abdominal distension is common after the first two or three days. Screaming attacks may be caused by colic.

In the absence of appropriate treatment the dehydration and weight loss progress rapidly, and pallor, weakness, and anorexia soon become extreme. Sclerema, a grave terminal sign, occasionally supervenes. In a state of such extreme weakness the aspiration of vomitus readily occurs, causing bronchopneumonia, which is often the terminal event.

Treatment

Not a moment should be lost in starting treatment in such an acute disease; for severe toxaemia, a prolonged illness, much difficult nursing, and possibly a fatal issue may thus be forestalled. Even such a potent drug as sulphaguanidine cannot be expected to give good results when it is not administered until the illness has lasted several days; but it is never too late to introduce it in liberal doses, as therein lies the main hope of recovery.

(*a*) *General.*—The following routine, in conjunction with sulphaguanidine therapy, has given very satisfactory results. It has the virtue of simplicity.

An initial purge has been dispensed with when diarrhoea has become established. Milk is entirely withheld, and 5% lactose or dextrimaltose water is given *ad lib.* every one and a half hours. If fluid amounting to 4 oz. per lb. of birth weight per day is not taken, the total must be made up to this amount by gavage. Such an ample fluid intake is essential to replace the excessive loss, and to ensure adequate renal elimination of that part of the sulphaguanidine absorbed from the gut and prevent its crystallization in the renal tubules and urinary tract. When there is much vomiting the sugar should be given in 1/5 normal saline instead of water. In severe cases the fluid may have to be introduced by stomach-tube for several days. A thin male catheter (No. 18 French) attached to the barrel of a 10-c.cm. or 20-c.cm. syringe may be used for this purpose. Only sugar and water or diluted saline should be given until the appetite returns; this may not occur for from several days to a week. It is a great mistake to introduce any milk until the general condition shows considerable improvement and the feeds are taken with some eagerness. Apprehension is often shown over such prolonged withholding of milk, but in the absence of a return of appetite there is no indication whatever for giving it sooner, and better progress is made without it.

The above regime, coupled with sulphaguanidine therapy, obviates the need for the parenteral administration of fluid except on rare occasions. Only one of the 30 cases treated with adequate doses of sulphaguanidine was given fluid parenterally. The frequent subcutaneous administration of saline was a routine procedure with former methods of treatment, and intravenous fluid was sometimes required in addition. The comparative ease with which severe dehydration can be prevented when sulphaguanidine is given is a measure of its efficacy.

The necessity for introducing milk gradually when the appetite returns must be emphasized. It is customary in this hospital to give it in alternate feeds in the form of either half-strength breast-milk or 1/12 sweetened condensed milk. The number of dilute milk feeds is slowly increased until milk is being given at every feed. Then the feeds are gradually strengthened according to the demands of the appetite. When convalescence is well established fresh milk should be substituted for sweetened condensed milk. The re-establishment of milk feeding in a premature infant is shown in Fig. 2.

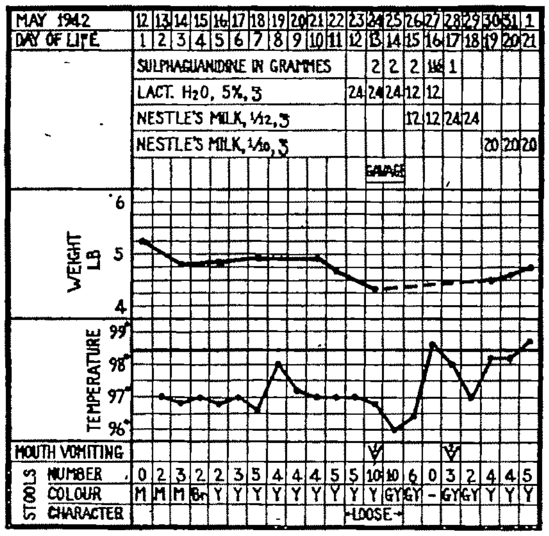

FIG. 2.—Clinical chart of baby, birth weight 5¼ lb. Epidemic gastro-enteritis developed on the eleventh day. The chart shows the course of the weight, temperature, and stools, and the treatment by starvation and with sulphaguanidine.

(*b*) *Sulphaguanidine.*—It is of the utmost importance to give full doses. Owing to its slow absorption from the bowel, and the necessity for achieving a high concentration therein, larger doses of this sulphonamide should be given than of the others. In this series of cases the mature infants received an initial dose of 0.75 g. tabloid sulphaguanidine, B.W. & Co., followed by 0.5 g. every four hours, and premature infants an initial dose of 0.5 g. followed by 0.25 g. every three hours. The latter dose is well tolerated by very premature infants provided ample fluid is given. These doses are continued for several days until there is pronounced clinical improvement with a return of appetite. It is then gradually reduced, being stopped a few days later (see Fig. 2). It was continued for as long as a fortnight in some of the cases in this series.

(*c*) *Prophylactic.—Immediate isolation* of all infants suspected of infective gastro-enteritis is an essential precaution in maternity hospitals. This dangerous disease should be suspected when an infant which has been feeding and progressing satisfactorily loses its appetite and shows diminished vitality and pallor. Confirmation of the diagnosis should be followed by strict precautions, to limit the extent and duration of the outbreak. There should not be any new admissions to the nursery in which the case occurred until all the contacts have been discharged. These contacts should be watched very closely for the first signs of the disease. Unless such strict measures to stamp out the infection are taken at its first appearance—and they are often neglected—an epidemic which will drag on for weeks or months may occur. Frant and Abramson (1938) have drawn up an excellent code of hygiene for the prevention and control of this and other infections in hospital nurseries.

Toxicity of Sulphaguanidine

Sulphaguanidine is one of the less toxic sulphonamides owing to its slow absorption from the bowel. This property enables very much higher concentrations to be attained in the bowel than in the circulation and other tissues of the body. About 20 to 25% of the drug is excreted in the urine. Acetylation does not occur in the intestine, but 20 to 50% of the assimilated drug is conjugated. After oral administration the maximal concentration in the blood is reached in about four hours, and most of the drug is excreted within 24 hours. Stickney, Heilman, Bargen, and Dearing (1942) found, in a series of 70 patients who were mostly adults, that with an average dose of 0.1 g. per kilo of body weight given every four hours the maximal concentration of free drug in the blood usually did not exceed 4 mg. per 100 c.cm., and seldom reached the level of 6 mg. per 100 c.cm.

The maintenance of a high fluid intake is important to eliminate the possibility of excessive concentration of the drug in the urine, with crystallization in the urinary tract. The urine of infants receiving the drug often contains a few characteristic crystals in the form of parallelogrammic plates, and needles occurring singly and in sheaves, but these should never be abundant.

A recurrence of frequent defaecation, which appeared to be a delayed toxic effect of sulphaguanidine on the bowel, occurred in 8 of the 30 infants. This phase began 8 to 10 days after starting with the drug, and subsided a few days later. The stools were small in bulk and normal in appearance. In some cases the drug was still being given, in others it had been discontinued for a few days. The diarrhoea had usually been controlled for a few days before the increased frequency of defaecation recurred. A return of frequent stools, provided they are normal, is no indication for continuing or resuming either drug or starvation treatment, as convalescence is uninterrupted.

In their series of 70 cases, mentioned above, Stickney *et al.* observed the following undesirable reactions: nausea 4, dermatitis 3; headache 2, indigestion 2, vomiting 1, and haematuria 1. The estimation of toxicity in the newborn must of course depend on the observance of signs such as dermatitis, vomiting, and haematuria. Agranulocytosis seems to be a rare complication with sulphaguanidine, but should always be watched for on account of its seriousness.

Comment

In computing the comparative death rates in cases treated with sulphaguanidine and those untreated, four infants who received the drug have been excluded. These four were among the first to be treated with the drug, and were given only half the dose which was afterwards found to be necessary for an optimal effect. Moreover, treatment of two of them was not begun until the fourth day. All four died, and it seems irrational, from a comparative standpoint, to include them in the group of cases all of which were treated in the standard manner recommended here.

The mortality rate in the series of 30 cases treated with sulphaguanidine would probably have been still lower if there had not been so many very premature infants. There were 11 mature and 19 premature infants, and 8 of the premature infants weighed less than 4 lb. at birth. The three fatal cases all belonged to the latter group. In addition to extreme prematurity two of the infants who died had complications which might have determined the fatal issue. One showed clinical signs of intracranial haemorrhage which were confirmed at necropsy, when both subdural haemorrhage from a fairly large tentorial tear and subarachnoid haemorrhage were found. It is reasonable to assume that this complication substantially reduced the chances of recovery from the gastro-enteritis which supervened on the tenth day. The other infant seemed to be responding well to treatment when its condition suddenly deteriorated, six days after the onset of the disease, and signs of bronchopneumonia developed. A necropsy showed that aspiration of vomitus had caused the pneumonia. As this infant was improving and beginning to feed well it would probably have recovered if the unfortunate accident of aspiration, which is commoner in premature infants, had not occurred.

Much work remains to be done on the action of various sulphonamide compounds in neonatal gastro-enteritis. More experience with sulphaguanidine is needed, and the action of sulphapyridine, sulphathiazole, and other compounds requires investigation. Sulphapyridine and sulphathiazole are valuable therapeutic agents in bacillary dysentery and some other alimentary infections, and may be beneficial in neonatal gastro-enteritis, but they are likely to prove more toxic to the newborn infant than sulphaguanidine.

Summary

The dramatic reversal of the prognosis in epidemic gastroenteritis of the newborn wrought by sulphaguanidine therapy has been demonstrated.

To achieve optimal results sulphaguanidine must be given in the full doses recommended.

An ample fluid-intake must be ensured. Fluid every 1½ hours is recommended. Tube-feeding may be necessary when there is anorexia. Parenteral administration is seldom required.

Milk should be withheld entirely until the appetite returns, and reintroduced very gradually.

I wish to express my thanks to Prof. Charles McNeil, paediatrician to the Simpson Maternity Hospital; to Dr. G. B. Ludlam, lecturer in bacteriology, University of Edinburgh, for personally examining many specimens; and to Dr. J. M. Robson, lecturer in pharmacology, University of Edinburgh, for helpful advice on the use of sulphaguanidine.

SCABIES TREATED WITH ONE APPLICATION OF BENZYL BENZOATE

BY

JOHN R. GRAHAM, M.B., D.P.H.
Medical Officer of Health, Chesterfield Rural District

Lately many articles have been published on the treatment of scabies by various methods, and many people still are insistent on the necessity for the disinfection of clothing and bedding by steam. In view of this the methods of working and the results obtained at the Poolsbrook Treatment Centre, Staveley, from Aug. 13, 1942, to Dec. 31, 1942, in treating approximately 1,000 cases of scabies are of interest.

The decision to treat the patients with only one application of 20% benzyl benzoate emulsion and to ignore entirely the fomites was taken after consultations with Dr. K. Mellanby, and the reasons for arriving at the decision were: (1) it would afford a practical test of Dr. Mellanby's hypothesis that fomites play only a very minor part in the spread of scabies; (2) the one-treatment method would economize in staff and save many hours of patients' time; (3) if clothing and bedding could be ignored the use of an extra car and driver would be saved.

Reasons 2 and 3 are important in normal times, but in war such economy is vital.

The centre serves the urban districts of Clay Cross, Dronfield, and Staveley, and the rural districts of Chesterfield and Clowne; accommodation consists of waiting-room, examination-room, and two bathrooms. The area covered is some 150 square miles, and the population served is 120,000. The boundaries of the district are 10 to 17 miles distant from the centre as the crow flies, and in the period mentioned the ambulance used for bringing the patients has travelled 8,100 miles.

The building chosen for adaptation was an empty shop with house attached and a large garage. The shop and house had four rooms on the ground floor; these were converted into the two bathrooms, waiting-room, and examination-room; on the first floor a bedroom was converted into a store-room. A sitting-room and a bedroom were kept for the supervisor's use. The premises had a 24-hour supply of hot water from the central heating plant supplying the Poolsbrook housing estate of the Staveley Coal and Iron Co. The water came through at boiling-point, so a thermostatic and a reducing valve were fitted to obviate any chance of scalding patients. Unfortunately it was not practicable to use this water for heating, so a domestic central heating plant was installed.

The following are the capital costs and maintenance expenses to Dec. 31, 1942.

Capital Expenditure

	£	s.	d	£	s.	d.
Adaptation of buildings, decoration, painting, black-out, baths, furnishing, etc.	254	15	5			
Central heating plant	150	0	0			
Towels, overalls, etc.	67	12	3			
Purchase and adaptation of ambulance	327	16	0			
Other initial expenses (medical appliances, typewriter, and sundries)	30	15	7			
				830	19	3

Maintenance Expenses

	£	s.	d.	£	s.	d.	£	s	d.

Maintenance and repair of premises, etc. ..					11	6			
							£405	1	2

The staff employed are a male supervisor, trained at the Sorby Research Institute by Dr. Mellanby, and two female attendants, one of whom acts as driver.

Routine

Patients are notified direct to the centre by the local general practitioners, school medical officers, health visitors, etc. On receipt of the notification a postcard is sent to the home stating that the ambulance will call at a certain time for the patient and all members of the household. On arrival at the home the driver-attendant inquires into the family spread of the disease, and has been most successful in getting whole families to accompany her to the centre. In most instances the adult members, if they should be out working at the time of the visit, can be persuaded to make a subsequent attendance at the centre.

On arrival at the centre the patients go to the waiting-room until called for examination. The history is taken, the hands and wrists are examined by the supervisor, and if possible a live mite is extracted and identified under the microscope. The patient then goes to the bathroom, has a hot bath, dries, and is painted from neck to soles with a 20% benzyl benzoate emulsion (N.W.F.) by an attendant using a 2½-in. paintbrush and paying particular attention to such areas as the gluteal folds. The emulsion is allowed to dry—about 5 to 10 minutes; the patient dresses and goes home. An appointment is made for him to return in a week's time for examination.

At the re-examination a mite is extracted, if possible, and examined under the microscope to see if it is alive or dead. (Live mites become quite active on a heated slide.) Inquiries are made regarding any clinical symptoms, etc., and if the supervisor thinks it necessary another treatment is given. If complaint of dermatitis is made, this condition is treated. In a previously untreated case no dermatitis has been observed after treatment with benzyl benzoate, but dermatitis has occurred in a number of cases which had previously been treated with sulphur and other medicaments. In treatment of dermatitis ung. hydrarg. ammon. dil. has been quite successful. Patients are always instructed to return immediately there is any recurrence of symptoms. Secondary infection is treated by the application of 2% gentian violet, with excellent results.

When school children have no gross secondary infection they are instructed to return to school after treatment. If there is bad secondary infection they are told to remain off school, and if on re-examination the condition has cleared they may return to school. If the secondary infection has not improved, the parents are told to take the case to their own doctor. A note is sent to the head teacher notifying him or her if the child is fit to return to school.

Results

In the following table all percentages have been calculated on the assumption that the 109 contacts had no scabies.

Cases treated (active scabies and household contacts) .	980
Active scabies	871
Relapses	8 (0.92%)
Gross No. of reinfections	20 (2.29%)
No. of reinfections where the whole family treated	10 (1.14%)
" " " " " not treated ..	10 (1.14%)
Total reinfection and relapses	3.32%

The possible causes of relapses and reinfection are: (1) contact with other cases of scabies; (2) reinfection from bedding or clothing; (3) failure of treatment. Reinfection from other cases is by far the most probable cause of relapses and reinfection.

Relapses are those cases which had symptoms persisting or had a live mite removed on re-examination. From an administrative point of view they are not important, as they are treated again. The rate of failure of one treatment with benzyl benzoate emulsion may be taken as 0.92% ; two treatments would almost certainly eliminate those relapses. Incidentally, all the relapses were found to have been in contact with untreated cases. Reinfections are cases which return after a lapse of 6 to 8 weeks with recurrent symptoms. The 10 cases in which the whole family group was treated were made up of 3 families of 3, 3, and 4 persons each. They came from areas where scabies was very prevalent, and one family of 3 members came into close contact with untreated cases. If it could be assumed that this family were reinfected from another case of scabies this would bring the rate of reinfection in whole family groups treated to 0.8%.

Conclusions

One treatment with benzyl benzoate will cure over 99% of cases of scabies if efficiently applied. Disinfection of clothing and bedding is unnecessary. At the most the omission to disinfect will only give an increase of reinfection of just over 1%, assuming the whole family group treated were reinfected from fomites. In the case of the districts served by the Poolsbrook Centre it is estimated "no disinfection" will save £700 per annum in transport charges alone. Disinfection of clothing, etc., at the isolation hospital would probably cost another £300. In time of war the use of man and woman work hours is entirely unjustified for any improvement that might accrue. Dermatitis has never occurred with one treatment of benzyl benzoate 20% emulsion in untreated cases. In many cases treated with sulphur, etc., before coming to the centre dermatitis has been observed. The success of the one treatment depends on having a skilled and competent staff.

Medical Memoranda

Perforated Oesophagus following Burns

A case of extensive burns was admitted recently into St. Mary's Hospital which proved fatal. Necropsy revealed perforation of the oesophagus 2 in. above the cardiac opening, with leakage of oesophageal contents into both pleural cavities.

Case Record

Mrs. A., aged 29, was unconscious when admitted in the early hours of Oct. 3, 1942. She had second-degree burns of the entire back, the back of the shoulders, and both buttocks, with areas of third-degree burning. The backs of the thighs were involved in a first-degree burn. The back of the neck also had a first-degree burn, as had quite a large part of the face. The hair was extensively burnt. Carbon monoxide poisoning coexisted, and the patient was transfused with two pints of blood. On removal to the theatre this was followed by three pints of serum, and the burn was treated by cleansing with saline and applying a tan with a 15% solution of tannic acid.

On the day after admission the patient seemed quite well. She complained, however, of a constant and quite severe pain between the shoulder-blades. In addition she had a persistent non-productive cough. The pulse was fairly steady at 120 and the temperature remained normal. On the second and third days the pain between the shoulder-blades increased and had to be controlled with morphine. She was restless and her cough increased. She began to bring up some frothy sputum. The temperature began to rise, and on the evening of the third day it was 103°. The patient died in the early morning of the fourth day after admission.

At necropsy there was no evidence in the tongue, lips, or pharynx of any corrosive poison having been taken. Two inches above the cardiac opening there was an erosion and perforation of the posterior surface of the oesophagus. The erosion was about 1/4 in. in diameter. The surrounding tissues were partially digested. The stomach contained green fluid and had as many as twenty small erosions on its walls. The duodenum had three similar erosions, but they were smaller. The liver was much enlarged, and weighed 2,500 g. It had undergone excessive fatty change. The lungs showed hypostatic congestion. The postero-lateral surface of the left lung was partially digested. The left pleural cavity contained half a pint of green fluid of the same appearance as the green fluid in the stomach. The right pleural cavity contained about a pint of purulent brown fluid.

I have to thank Prof. Newcomb for the necropsy report, and my chief, Mr. Duncan C L. Fitzwilliams, for asking me to publish the case.

L. C. Robson, M.R.C.S.

Dermatitis after Local Sulphanilamide Treatment of a Wound

The following case is reported as one of clinical interest relating to sulphanilamide sensitivity produced by prolonged local treatment of wounds with the drug in its powder form.

Case Record

An officer recently came under my care for a graze of the left buttock and left elbow, sustained in a severe fall. The wound of the elbow was only a shallow one, and it was considered that acriflavine dressings were all that was necessary. The wound of the buttock, on the other hand, was rather deeper, and 1 in. in diameter. I decided to dress this with sulphanilamide powder. Local application was employed, none of the drug being administered orally. Five grammes of the powder were applied, being left *in situ* for 24 hours. At the end of this time the patient said that his left knee was irritating slightly, and on examination the skin over that joint was found to be somewhat reddened, but nothing more. A further 5 g. of the powder was applied, and 12 hours later he reported a very severe irritation of this knee and that it was discharging. On examination it was found that the skin over the left knee was very red and was covered with numerous small papules which were exuding a thin, sticky mucous fluid. He now volunteered the following history:

Eighteen months previously he had fallen, and suffered a severe graze of the left knee. This was treated with sulphanilamide powder 5 g. daily for 2½ months before it healed. At the time of this treatment there was no dermatitis. Three months later he developed an acute follicular tonsillitis and was admitted to hospital. This was treated with sulphanilamide tablets orally—2 g. immediately, followed by 1 g. every four hours. Within 48 hours of the start of this treatment he noticed an irritation of his left knee, and in 56 hours a rash had developed exactly similar to the one experienced during his treatment under me. The area affected with the dermatitis was in all cases exactly that involved by the original graze of the left knee. In each instance the dermatitis was easily cured by stopping the sulphanilamide and by the local application of calamine lotion.

Here apparently is a case of sensitivity to sulphanilamide persisting for 15 months after prolonged local treatment with the drug in its powder form, without any other form of the drug being administered during the intervening period.

Ian M. Macgregor,
Fl Lieut., R.A F., Middle East Forces.

Reactions to Ephedrine

Severe reactions to ephedrine are uncommon, but reactions in persons who had previously taken the drug without discomfort are most unusual. The following two cases may prove of interest.

Case 1.—This girl, aged 12, developed a chronic maxillary antritis. In the course of treatment she had often used a spray of 2% ephedrine solution and taken up to 3/4 gr. of ephedrine internally in one day. In Oct., 1940, she had had several treatments by suction technique, in which 1 c.cm. of 0.5% ephedrine solution was dropped into the nose while she lay with head extended. No adverse effects were observed. In Nov., 1940, she had a further treatment, in which 1 c.cm of ephedrine solution of 1% strength was used. Half an hour later she felt shivery, and dry in the throat. She complained of her heart beating violently, and grew very restless. When seen she was frightened, flushed, and unable to lie still. Her respiration rate was 42 and her pulse rate 180. With sedatives her condition returned slowly to normal in four hours, and next day she was none the worse.

Case 2.—This patient, a boy aged 6, is an allergic type. He suffers frequently from asthma, hay-fever, and eczema. The family history records allergic conditions on both sides. His mother shows similar reactions to her son's, and his father produces severe reactions to infections of the respiratory passages. The boy has had ephedrine in various forms, taking up to 3/4 gr. a day without ill effect. In April, 1942, he developed a catarrhal infection of the nasopharynx and started to wheeze He was given 3/8 gr. of ephedrine sulphate combined with 3/4 gr. of amytal. (At the age of 4 he had taken half this dose three times in 24 hours without discomfort.) Soon after this administration, however, he became very restless and frightened, and refused to be left. He complained of thirst and drank water copiously. His respirations became very rapid and his pulse uncountable This condition of hyperexcitability slowly subsided, though two hours later his pulse rate was 178 and his respiration rate 40; but after a sedative he went to sleep. Next morning his pulse rate was still faster than normal, but this may have been due to the mild pharyngeal infection.

Such violent reactions to ephedrine in normally tolerant children seem at present to be inexplicable; they are certainly alarming to child, parent, and doctor, and show the necessity for care in the administration of the drug.

R. A. Murray Scott, M.B.

Reviews

HAEMORRHAGIC DISEASES AND HAEMOSTASIS

The Hemorrhagic Diseases and the Physiology of Hemostasis. By Armand J. Quick, Ph.D., M.D. (Pp. 340. $5.00 or 27s. 6d.) Springfield and Baltimore: Charles C. Thomas; London: Baillière, Tindall and Cox. 1942.

Great advances have been made in the last decade in knowledge of the haemorrhagic diseases. Dr. A. J. Quick has himself made notable contributions to this knowledge. He has now written a concise account of the mechanism of haemostasis and the diseases in which a bleeding tendency is the major problem. His monograph is beautifully produced and reasonably priced. The complexity of the subject is shown by the fact that he makes reference to over 1,000 original articles, and this is probably the best simple account of what is assuredly one of the most difficult subjects in medicine. Quick is a vigorous protagonist of the classical hypothesis of blood coagulation—that prothrombin and calcium react with thromboplastin to form thrombin, and that the thrombin then reacts with fibrinogen to form fibrin. This hypothesis has justified itself by such rewards as the discovery of the cause and effects of hypoprothrombinaemia, the introduction of vitamin K and dicoumarin, and the clinical application of powerful haemostatics, such as snake venom and stable thrombin. Quick proceeds in a series of lucid chapters to describe prothrombin, thrombin, fibrinogen, thromboplastin, the platelets, and the anticoagulants. There then follow descriptions of the classical haemorrhagic diseases—purpura haemorrhagica, the hereditary haemorrhagic diathesis, fibrinopenia, haemophilia, and the haemorrhagic diathesis of vitamin K. It would be difficult for anyone to write a better introduction to the subject, and people thinking of carrying out research on blood coagulation or adding to the already voluminous literature would do well to study this book first of all. The uninitiated reader may well think that the problems are simpler than they really are. Experience of the difficulties of storing stable blood products at a transfusion depot and clinical study of unselected cases of haemorrhagic disease will not be long in proving to our beginner that there is still much to learn. He may well begin to doubt whether the effects on the plasma of extrinsic factors, foreign surfaces, filtration, hydrogen-ion concentration, etc., are really explained by the classical theory of blood coagulation. His biochemical colleagues will show themselves a good deal happier about the colloidal chemistry of muscle contraction than that of blood coagulation. He will find that spontaneous haemorrhage is much more commonly due to infection, toxaemia, and avitaminosis than to the classical haemorrhagic diseases, and a good deal more difficult to explain. He will be puzzled to observe that a boy with fibrinopenia and a practically incoagulable blood seems a great deal less inconvenienced than a haemophiliac whose blood clots in 15 minutes. He may even begin to wonder whether we know anything at all about the part played by the capillaries and the tissues in haemostasis. He will then realize the artistic simplicity of Dr. Quick's book, and will be well advised to study it again more carefully. For it is indeed a most able summary of what is known about the mechanism of haemostasis, and its only real fault is that it suggests that we know far more than we do.

MASS MINIATURE RADIOGRAPHY

Mass Miniature Radiography. By R R Trail, M D., F.R C.P., H. J Trenchard, M B., M.R.C P., and J. A. Kennedy, M.B. B S. (Pp. 96; illustrated 8s 6d) London: J. and A. Churchill. 1943.

The publication of *Mass Miniature Radiography*, by R. R. Trail, H. J. Trenchard, and J. A. Kennedy, is very timely. The authors have had a large practical experience of mass examination of the chests of R.A.F. personnel, and the organization and technique for civilian mass radiography that they outline in this book are based on that work. There is a foreword by Lord Dawson—appropriately, in view of his warm advocacy of the adoption of mass radiography as a public health measure. It is pleasant to think that his advocacy has recently had so successful a result. The authors in the preface say that the book is intended as a practical guide to the setting up and running of a mass miniature radiography department. In this they have succeeded admirably.

In the first two chapters administration and central administration are considered. In miniature radiography of the chest the highest technical quality must be maintained. An indifferent miniature radiograph is worse than useless; it is misleading. That the authors appreciate this is indicated by their insistence on central co-ordination to ensure a high standard of work throughout the country. The next three chapters deal with accommodation, apparatus, and staff. A plan of a model department is given, and two types of apparatus are described. The authors prefer an apparatus with as few interlocking safety devices as possible, but, provided that these devices translate silent faults into an obvious failure on the part of the unit to function, they are an advantage and avoid the necessity for recalling subjects for re-examination. The authors point out that a considerable staff (between five and nine) is required to operate these units. This may deter hospitals which contemplate installing a unit merely for its publicity value.

The lay-out of *x*-ray and dark rooms and the processing of films are described, and due stress is laid on the necessity for adequate protection of the staff. A particularly valuable section is that on the routine of working a department, including the system of records and disposal of suspects. The book contains a chapter on interpretation of films, and appendices on classification, record cards, and accessory equipment.

Although there are some points of detail in it that not all will agree with, this book is to be particularly welcomed just now, and is recommended to all interested in the subject. It will be invaluable to those who will shortly have the duty of organizing mass radiography centres throughout the country.

CLINICAL ANAESTHESIA

Recent Advances in Anaesthesia and Analgesia (Including Oxygen Therapy). By C. Langton Hewer, M B., B S., D.A Fourth edition. (Pp. 341; illustrated. 18s.) London: J. and A. Churchill.

Anaesthetists everywhere must be glad that a fourth edition of this book has been published. Dr. Hewer in his preface emphasizes that he has deliberately omitted a special chapter on anaesthesia for the surgery of the battlefield or the bombed town. In this he is wise, since the principles of anaesthesia are the same, and in both peace and war the main short cut to good anaesthesia is an unobstructed airway. As every anaesthetist knows, this volume contains an enormous amount of information on clinical anaesthesia, compressed but readable and easily available for consultation. Dr. Hewer has managed to include his own opinion on most major problems, so that the inexperienced need not flounder in a bog of assorted views when needing guidance. It is, however, apposite, now that we have a diploma in anaesthesia, to point out that this is not a textbook. Elementary facts and commonplace well-tried methods are in fact often deliberately omitted. What might be included in a future edition are descriptions of some of the better-known techniques for regional nerve block, such as brachial and cervical plexus blocks, and paravertebral block for abdominal operations. There seems to be an unnecessary amount of space devoted to listing local anaesthetic drugs, most of which are now of academic interest only. A complete list of references is given at the end of each chapter, and the isolated anaesthetist should not hesitate to employ this guide to wider reading before either using or passing judgment on a method with which he is unfamiliar.

As heretofore, the book is well produced, particularly so for these days.

Notes on Books

Physiological Psychology, by S. R. HATHAWAY (New York and London: D. Appleton-Century Company; 15s.), is a simply written elementary account of the structure and functions of the nervous system, and is intended for psychologists. The presentation, if rather dry, is clear and comprehensive. We are a little surprised to find, however, that so small a space is given to the physiology of the conditioned reflexes. One would suppose that it is the upper levels of the nervous system in which psychologists are most interested, but it is certainly very desirable that they should have some appreciation of the ways in which the lower levels are constituted and how they function, and for such a purpose this book is well designed.

PSYCHOGENIC FACTORS IN BRONCHIAL ASTHMA

The term "psychosomatic medicine" has become very popular, and there is now at least one journal devoted to this topic. Since psychological medicine is so often accused unjustly of being clogged with esoteric technical terms it behoves us to investigate any neologism carefully to see that its introduction is justified. There is a practical usefulness in the term "psychosomatic" if it calls the attention of doctors to what they have often been unaware of in the past—namely, the effect of personal events in producing symptoms with a physical reference, and even, in the case of individuals with a *locus minoris resistentiae,* in facilitating the occurrence of physical disease. Indeed it has been observed in a search for control material that among a group of individuals with ordinary physical illness the onset of their illness often coincided with a period of personal stress, as if the psychophysical chain had broken at its weakest link. One of the conditions that has been most studied in this connexion has been asthma, which is an interesting disease for a variety of reasons. Its manifestations appear to be invoked not infrequently by mental disturbance, and it is one of the rare examples of a functional disorder which by repetition leads to structural organic damage.

In this *Journal* several years ago R. D. Gillespie enumerated the possible interconnexions of asthma with psychological factors.[1] It was tentatively suggested that in rare instances the asthmatic attack might have a symbolic value, being chosen automatically as a pattern of expression because the asthmatic paroxysm in some way reproduced the unconscious imagery of the underlying conflict. But no satisfactory evidence was produced at the time, and the author confined his examples to cases in which emotional factors played in an unspecific way on a physical predisposition. In a painstaking study French and Alexander[2] have propounded the thesis that the asthmatic attack is the equivalent of a suppressed cry. The asthmatic patient, in their view, is one who has been frustrated in his affections in early life and forbidden to cry, crying being the infant's natural call for sympathy. Unfortunately the evidence for this ingenious theory seems thin indeed and rather too characteristic of some types of psychological speculation: what begins as a hypothesis in one chapter ends as an established fact two chapters further on, without much intervening substantiation.

More in accord with general experience and more in conformity with what most people will find understandable are the observations of Sir Arthur Hurst, whose long experience of the conditions has been subjective as well as objective. An article from his authoritative pen appears at the opening pages of this week's issue. On the one hand, according to Hurst, there is the asthmatic diathesis or constitution, and on the other the numerous precipitating factors, some of them psychological. The factor of constitution, especially if it can be shown to be supported by data on heredity, is one that is more acceptable on general principles than the psycho-analytical notion of asthma itself as an essentially symbolic matter. One point where Hurst finds psychological factors of outstanding importance is in the alleviation of asthma. It is here that a knowledge of medical history shows its value. There would be less tendency to claim results from new nostrums if their pedlars were historically informed. The history of asthma in medicine is the history of one "successful" cure after another; yet asthma remains and "cures" multiply wherever a number of physically diverse remedies are equally effective. The common factor of suggestion is the preponderant one.

The investigations of French and Alexander support and extend the previous findings of Rogerson (who also contributes a note on the subject at p. 406), Hardcastle, and Duguid, by analysing further the influences behind the anxiety and aggressiveness that these observers had noted as characteristic of asthmatic children. Cameron had long ago observed the effect of maternal over-protection in this setting. Asthma is in fact a kind of "experiment of Nature" on the combined effects of physical and psychological causes from a wide diversity of spheres—constitutional, accidental, physical, educational, and emotional. The study of asthma is an admirable antidote to those whose disposition tempts them to accept uncritically the last new thing discussed in the market-place of medicine.

INTRAVENOUS ALIMENTATION

The possibility of feeding by complete parenteral alimentation patients who cannot ingest, digest, or absorb foods properly is most attractive. The intravenous administration of glucose solutions to meet the energy requirements of such patients is, of course, an established practice, and some success has also been achieved with the injection of emulsified fats[1]; but only recently have man's nitrogen needs been supplied in this way. Theoretically, intravenous protein alimentation should be quite a straightforward proposition, for, although proteins are the normal nitrogen-containing materials ingested by the individual, the amino acids obtained from these proteins by enzymatic digestion are the fundamental units which his body manipulates in satisfying its needs. Obviously, then, it should be possible to eliminate the processes of protein digestion in and amino-acid absorption from the alimentary canal by the simple expedient of introducing the necessary amino acids directly into the blood stream. Elman and Weiner, who succeeded in doing this in 1939,[2] used an acid hydrolysate of casein supplemented with tryptophane and methionine or cystine. After preliminary successful trials on adult dogs, they administered the supplemented digest intravenously to patients suffering in general from some form of obstruction of the alimentary canal. The large negative nitrogen balances of these patients were corrected and they were able to store nitrogen. These results were promising enough, though the amino-acid mixture used was not particularly ideal, since the supplements were expensive. Elman and a number of other clinicians[3 4 5 6] then experimented with an enzymatic digest of casein—amigen—which retained its full complement of tryptophane. Intravenous injections of solutions of this substance were well utilized and required no further amino-acid supplements, but there were at first a few undesirable reactions. A too rapid rate of injection caused abdominal pain, nausea, and vomiting; these symptoms were not seen when the injections were given more slowly. Chills and fevers were frequently encountered, but Elman and his colleagues[4] found that these could be eliminated, as they were merely associated with pyrogens of bacterial origin present in the distilled water used for making the amigen solutions. Phlebitis was a more constant reaction, but Elman[4] and Landesman and Weinstein[6] consider that amigen solutions are really no more irritant than similar solutions of glucose and of salts. Of some 500 patients, many of them in a critical condition, to whom the solution of amigen was given, only two showed any urticarial response, and of the few deaths recorded none was caused by the amino-acid mixture. On the other hand, the indications were that without the amino-acid injections the death rate would have been higher, though objective proof of this fact was unobtainable. All the evidence shows that the intravenous injection of a sterile 2.5% solution of amigen prepared in freshly distilled water and administered at the rate of 8 to 12 g. of solids per hour is a safe procedure, and a simple and convenient way of supplying large amounts of protein nourishment parenterally. The amino acids so administered are well utilized, pronounced negative nitrogen balances are rapidly reversed, and a general improvement in the patient's clinical condition is observed. It is interesting to note that Clark and Brunschwig[7] have advanced intravenous alimentation a stage further by administering emulsified fat as well as dextrose and amino acids to a human being over a 17-day period, as much as 12 g. of nitrogen and 1,700 calories being given during one 24-hour period.

The diverse pathological states in which intravenous amino-acid alimentation has been used in America indicate the potentialities of this method. For example, it has been found beneficial in carcinomatous and ulcerative conditions of the alimentary canal, in cases of general peritonitis, in pneumonia and tuberculosis, and for burns. Elman and his co-workers recommend it for improving the nutritional state of undernourished patients before operation and also in the immediate post-operative period. Landesman and Weinstein suggest that the use of amigen is not limited merely to starving patients in whom it is impracticable to give protein by the intestinal tract. On only one point does there appear to be any controversy. Landesman and Weinstein do not consider that intravenous amino acids raise the low plasma protein levels of oedematous patients, while Elman and his colleagues hold the opposite view. Further trials over longer periods will probably settle this point. Shohl and Blackfan[8] have been successful in maintaining positive nitrogen balances in infants by intravenous administration of a mixture of 20 crystalline amino acids instead of protein digests. At the moment, however, this method is far too expensive, and in any case can only become really economical when it has been decided which of the amino acids are "essential" for the human species and which can be safely dispensed with.

VITAMINS AND PHYSICAL FITNESS

Some months ago we wrote in these columns[9] of work done in America on the relation of vitamins to bodily efficiency. To this information from the other side of the Atlantic, which, *inter alia*, underlined the excellence of American Army diets, may now be added experience gained at home by Harper, Mackay, Raper, and Camm, whose results were recently published in this *Journal*.[10] Experiments were carried out at Manchester University on the effect of treatment with vitamins A, D, and C on the fitness of R.A.F. and R.E. cadets. The young men, 69 in all, lived in two university halls and had the ordinary undergraduate diet. A preliminary examination was done, which consisted of collecting the usual anthropometric data and of measurements of the resting and standing heart rate, of the resting and post-exercise vital capacity, and of the R.A.F. breath-holding and endurance tests. The cadets were then divided into two groups, and members of one group received daily a capsule containing 6,000 units of vitamin A and 1,000 units of vitamin D and a 50 mg. tablet of vitamin C, while the remainder were given placebo capsules and tablets. After 10 weeks the men were re-examined and the two groups were changed over for a further experimental period of 11 weeks, ending with a third examination. The results of the tests were statistically examined, and it was found that at each comparison the performance of the men receiving the vitamin additions was in several respects superior to that of the cadets given the sham treatment. Thus the measurements of resting vital capacity, of the breath-holding time, and the endurance tests were in their favour at both re-examinations, and the combined differences taken over the whole period were statistically significant. The effect of the vitamin additions was also reflected in changes in the resting heart rate, but in a rather unexpected fashion in that a slower heart rate popularly taken as a sign of physical fitness was found in whichever group was on the control treatment. No significant differences were found in the standing heart rate, the post-exercise heart rate, the heart rate during the R.A.F. endurance tests, and the post-exercise vital capacity. Neither were the anthropometric measurements different. An interesting feature was the greater incidence among the controls of minor respiratory and gastro-intestinal complaints. The assessment of these differences was naturally more vague than for the physical measurements, as it rested solely on statements of the cadets themselves. These, however, did not know whether they were receiving sham or real treatment, and the differences were large—14.9 days per man of various complaints among the controls and 9.7 days per man in the vitamin-treated cadets—and statistically significant.

Harper and his colleagues have soberly assessed the results of their findings and are well aware of certain possible objections to their tests. It might be well to mention another. In two respects, the breath-holding time and the endurance test, differences between the two groups at the initial examination are rather large and may raise doubts as to the randomness of the original distribution.

In a shot-gun vitamin experiment it is generally impossible and always difficult to separate the effects of the different vitamins. Here, however, one is tempted to speculate that the relatively rapid tailing off of the vitamin group when switched over to control treatment points to an initial shortage of vitamin C, which cannot be stored for long, rather than of vitamins A and D, which would accumulate in sufficient quantity to allow of a longer carry-over during the lean period. Whatever the limitation of the diet of the cadets, it apparently became much less obvious in the second period; the vitamin and control groups were changed over at the end of June, and the treatment differences from then till September were much smaller than during the first round between April and June. This may have been connected with the usual improvement in the diet which takes place in the early summer.

One could wish that this useful experiment had been on a more ambitious scale, that it had included treatment with the vitamin B complex, and that the composition of the cadets' diet and an assessment of their bodily reserves of vitamins had been made available. It is to be hoped that this interesting piece of research at Manchester is a forerunner of more elaborate investigations. It has certainly rendered great service in showing that the diet of young men preparing themselves for most arduous duties is something that can be improved upon.

EPIDEMIC KERATOCONJUNCTIVITIS

Ophthalmological literature contains many reports of epidemic outbreaks of conjunctivitis complicated by corneal lesions. These date back to 1889, when von Stellwag recorded an outbreak described as "a peculiar form of corneal inflammation," and designated the appearances as "nummular" because of the multiple coin-like scars in the cornea. Such outbreaks have appeared at irregular intervals until the past few years, when widespread epidemics have been reported with increasing frequency in different countries both on the Continent and in the United States. As the condition is only now being clearly recognized, it was inevitable that the outbreaks should be recorded by different observers under a variety of names—such as superficial punctate keratitis, keratitis subepithelialis, keratitis maculosa, Béal's conjunctivitis, acute follicular conjunctivitis, and various nondescript designations. An excellent survey of this diffuse literature is given by Hogan and Crawford,[1] who include an account of 125 cases which they have studied. It is, of course, possible that not all the epidemics in the literature fall into this group. It is only necessary to recall the old conflict about the unity of trachoma with follicular conjunctivitis to appreciate that epidemic conjunctivitis with corneal lesions may constitute more than one entity. There is, however, strong evidence that a protean affection which has many manifestations must be regarded as a distinct clinical entity. The conjunctiva shows a number of lesions; it may be slightly involved or so severely affected that there is intense chemosis, especially in the lower palpebral area; or there may be mild follicular reaction or pseudo-membrane formation. As for the cornea, the designations of superficial punctate keratitis, macular keratitis, subepithelial keratitis, nummular keratitis, and diskiform keratitis are indicative of the varying conditions seen. What stamps the group as an entity are the cardinal points which are present in all cases: (1) sudden onset with glassy oedema of the caruncle, semilunar fold, lower fornix, and bulbar conjunctiva; (2) the severity of the conjunctival signs in the absence of any marked discharge—a point of considerable importance; (3) enlargement of the pre-auricular and other regional glands; (4) the frequent involvement of the cornea, shown subjectively by a worsening of the symptoms; (5) the absence of causative organisms in smears and cultures; (6) the presence of a lymphocytic type of exudate in smears and scrapings instead of a polymorphonuclear exudate common in other forms of acute conjunctivitis. Different observers have reported a varying incidence of unilateral inflammation even in severe epidemics, and it would appear that at least 50% of the infections are unilateral, while corneal lesions are generally present in about 75% of cases. The affection runs an acute course, but corneal damage may persist for months or permanently.

Aetiologically a large number of organisms have been incriminated but none established. The similarity of the corneal lesions to the herpetic affections of the cornea has led some workers to postulate a virus origin. R. E. Wright,[2] who was the first to recognize that extensive variations appear in superficial punctate keratitis, also brought forward evidence of the virus nature of the infection. Other observers have reported on similar lines, and Sanders[3] has now recorded some preliminary observations on the isolation of a virus agent in the epidemic that recently occurred in the shipyards of San Francisco, accounts of which have been reported by Hogan and Crawford[1] and by Rieke.[4] Most observers agree that treatment has little effect on the course of the disturbance, and reliance must be placed on palliative measures, including atropine when the cornea is involved. Silver nitrate in particular seems to be ineffective.

Some interesting theoretical speculations emerge from the clear recognition of this affection. Should it prove to be a virus disease, one further group of virus infections of the conjunctiva will have to be added to the established entities of trachoma, inclusion conjunctivitis of the newborn, and swimming-bath conjunctivitis. The relation of these different affections to each other and to herpes keratitis is a problem that promises to enlarge our knowledge of a difficult field of study.

TREATMENT OF TETANY IN PREGNANCY

That there is a drain on maternal calcium to meet the requirements of the foetus has long been recognized, and it is perhaps surprising that fully developed tetany is not encountered more often in association with pregnancy. Steinheim[5] in 1830 described a form of tetany associated with pregnancy and lactation, and with the advent of thyroidectomy, first performed by Kocher in 1878, a new aetiological factor for hypoparathyroidism appeared. Kehrer[5] in 1913 reviewed 103 cases in the literature and added 5 of his own. Recently Anderson and Musselman[6] have collected 240 cases, which they divide into four aetiological groups. In the first group were 26 post-operative cases, in some of which tetany developed during pregnancy although the parathyroid deficiency had not been severe enough to cause it in the non-pregnant state. This agrees with the experimental work of Dragstedt, Sudan, and Phillips[7] on bitches from which the thyroid and parathyroids had been removed and which developed tetany when they became pregnant. Those cases in which the mother survived usually resulted in death of the foetuses and abortion. The next two groups, with a total of 154 cases, were less certain in aetiology, and are described as being idiopathic, and having low calcium intake or vitamin D deficiency, respectively. Hyperventilation and blood loss during labour are regarded as possible aetiological factors, and lactation is thought to play a part since 41 of these cases occurred during that period. The fourth group consisted of 60 cases of thyroid disease, but little mention is made of them except that treatment of the thyroid condition was essential.

Although fully developed tetany is unusual in pregnancy, Anderson and Musselman maintain that the paraesthesias and "leg cramps" of many pregnant women are indications of impending tetany, while Ellsworth,[8] studying the blood chemistry of such patients, finds values of serum calcium below 8.5 mg. and serum phosphorus above 4.5 mg., which he regards as criteria of hypoparathyroid insufficiency. Richardson,[9] on the other hand, observed values of serum calcium as low as 5.6 mg. without subsequent symptomatology. Clinically, the diagnosis of subtetany and even of the fully developed disease in pregnant patients is not easy. Chvostek's sign is positive in 75% of all pregnant women in the latter weeks, and the cathode closing contraction in 80%, illustrating an increase of neuromuscular excitability. Brougher[10] believes there may be a relation between pre-eclamptic toxaemia and parathyroid insufficiency, and gives examples suggesting that parathyroid extract is deserving of further trial in the treatment of this condition. In any case the aim of treatment in tetany and subtetany is to raise the blood calcium and lower the serum phosphate. This may be achieved by intravenous or intramuscular calcium gluconate—10 c.cm. to 20 c.cm. of a 10% solution—and parathormone. After the acute stage, 25 g. to 30 g. of calcium lactate dissolved in warm water should be taken daily by mouth. It is also beneficial to place the patient on a low phosphorus diet by limiting the intake of meats, cheese, and egg-yolk. Vitamin D was the most effective agent in increasing the intestinal absorption of calcium until the discovery of dihydrotachysterol (A.T.10) by Holtz.[11] This also increases the phosphorus excretion, but it is not without its dangers, such as calcification in the kidneys, and during its administration the serum calcium must frequently be determined. Finally, Anderson and Musselman consider that tetany is no indication for the induction of abortion, as modern therapeutic measures are capable of saving both mother and child.

SILVER NITRATE FOR ASEPTIC OBLITERATIVE PLEURITIS

The production of an artificial obliterative pleuritis is important in the management of certain chest diseases, and in a recent paper Brock[12] describes the use of silver nitrate for this purpose. Adhesions between lung and parietes may be needed: (1) as a preliminary to lobectomy; (2) as a preliminary to suction drainage of a tuberculous cavity—Monaldi's operation; (3) to cure the condition of chronic or recurrent spontaneous pneumothorax; and (4) to relieve the condition of chronic idiopathic pleural effusion. Bethune's "pleural poudrage,"[13] in which iodized talc powder is blown into the chest through a cannula under thoracoscopic control, has been widely used for producing pleural adhesions before lobectomy, but the silver nitrate method has certain advantages over it, not the least being that it is a simple bedside procedure and not even a minor operation. A preliminary injection of morphine is desirable as there is some immediate pain. Then 7.5 to 10 minims of a 10% solution of silver nitrate is injected with an all-glass syringe after induction of a small pneumothorax, and as much air as possible is at once removed. There is usually a low febrile disturbance lasting 3 to 5 days, and some fluid is formed. This and any remaining air must be aspirated so that the pleural surfaces can adhere. After 3 to 4 weeks artificial pneumothorax is again attempted, and if successful (usually incomplete) a second injection is given. Out of 20 cases in which this method was used before lobectomy there was complete pleural obliteration in 15, and partial obliteration in 2 more; 13 of these patients had received one injection, and 4 had had two. The adhesions found at operation are ideal, being soft and avascular but firm enough to prevent collapse of the remaining lobe.

Chronic and recurrent (often bilateral) spontaneous pneumothorax is not at all common and can be very disabling. Brock mentions 32 cases, in 20 of which he used silver nitrate, and all 20 were cured. After preliminary thoracoscopy to exclude any lesion, such as congenital cystic disease, which may require other treatment, the silver nitrate is injected and expansion of the lung aided by subsequent aspiration of fluid and air. In one case the patient had had a chronic pneumothorax for as long as nine years; in all cases the condition had been present for some months. Patients with recurrent pneumothorax had had as many as half a dozen attacks, often on alternating sides and in some cases on both sides simultaneously. Brock also describes two cases of idiopathic massive pleural effusion in which successful pleural obliteration was secured after aspiration of all the fluid under thoracoscopic control and then introduction of silver nitrate. This was followed by repeated aspiration of fluid, the amounts rapidly diminishing until pleural symphysis occurred.

KETOSIS AND GONADOTROPHIN SECRETION

While oestrogens have been extensively used for the suppression of hypophyseal secretion, no therapeutic procedure has yet been developed for the stimulation of the pituitary. Last year, however, Julesz[1] suggested that a ketogenic diet would stimulate the secretion of gonadotrophin and perhaps of other pituitary factors. He was led to make his experiments by observations recorded in the clinical literature suggesting that women on such a diet frequently suffered from amenorrhoea. He accordingly put fourteen patients on a ketogenic diet (ten women and four men), and tested their urine by injection into immature female mice. The patients were sexually normal, with no evidence of endocrine disturbance; they mostly suffered from arthritis or asthma. The urine was injected by the usual Aschheim-Zondek procedure, a total of 3.6 ml. being given in six injections. Follicle stimulation was produced by the urine of twelve of the fourteen patients, this stimulation being very marked in some cases. No such effect was obtained by the urine of the patients before or after the period of treatment. That this excretion of follicle-stimulating gonadotrophin was associated with the ketosis is shown by the fact that two diabetics with ketonuria and one patient with starvation ketosis also excreted the hormone. The amenorrhoea seen in women during ketosis is explained as being due to over-production of follicle-stimulating gonadotrophin and the failure of the cystic follicles so produced to become luteinized, the endometrium remaining in the proliferative phase. The author goes on to suggest that all pituitary functions are stimulated by ketosis; that the capacity of the hypophysis to react when dysfunction is suspected may be tested by placing the patient on a ketogenic diet; and, finally, that the production of follicle-stimulating gonadotrophin on a commercial scale may be accelerated by application of his findings. Though these conclusions are hardly justified by the evidence, the facts are themselves interesting, and, if confirmed, should have wide application. It is, however, perhaps hardly practical to recommend the widespread adoption of ketogenic diets during the war.

The new Fellows elected to the Royal Society include Patrick A. Buxton, director of the Department of Entomology, London School of Hygiene and Tropical Medicine; Ivan de Burgh Daly, professor of physiology, Edinburgh University; A. J. Ewins, director of research, May and Baker, Ltd.; Arthur Felix, bacteriologist, Lister Institute; Alexander Fleming, professor of bacteriology, St. Mary's Hospital; G. A. R. Kon, research professor of chemistry, Royal Cancer Hospital; Wilder Penfield, director of the Montreal Neurological Institute; and S. Zuckerman, professor of anatomy, University of Birmingham.

OUT-PATIENT ORGANIZATION

A SUCCESSFUL APPOINTMENTS SYSTEM IN A FRACTURE CLINIC

BY

F. S. A. DORAN, M.A., M.B., B.Chir., F.R.C.S.
Resident Casualty Officer, Manchester Royal Infirmary

The hospital system of this country is undergoing a process of readjustment to enable it to provide a service to the community which when judged by modern standards will be considered efficient. At present several bodies are striving to become the dominant power in our hospital system. All those responsible for the direction of medical opinion should be aware that a system is only likely to succeed, and endure, in practice if it is based on conclusions drawn from the practical experience of the personnel concerned.

The main object of the personnel of the hospitals must be to provide an efficient service. Howarth (1939) is correct in saying that "it has for a long time been a reproach that at the large London hospitals, in which very considerable numbers of out-patients are dealt with each day, the patients may have to wait, and indeed often do wait, many hours before their case is finally attended to." This disregard of the length of time a hospital out-patient is kept waiting is based upon the opinion that those who cannot pay with money must do so with their time. This is a short-sighted policy: the majority of hospitals are to-day dependent to some degree on contributory schemes, personal donations of their patients, and the efforts of their almoners.

Howarth described the appointments system employed in the ear, nose, and throat department of St. Thomas's Hospital. I understand that it worked satisfactorily before the war. Somewhat similar systems have been attempted at University College Hospital, the Royal Hospital, Sheffield, and the Manchester Jewish Hospital. In this article I describe an efficient method of organizing out-patients.

The Method Employed in the Fracture Clinic of Manchester Royal Infirmary

Type of Material.—The average number of fractures treated each year is about 2,500. The Table, which is constructed from the Infirmary Statistical Report for 1938, shows the number of fractures treated (2,573) and their types. In this clinic all fracture cases are treated as out-patients; in-patients are dealt with in another clinic. The clinic is held each morning except Thursday and Sunday. New fractures admitted to the hospital during the morning are radiographed and seen with their films at the end of the clinic. Reductions are not performed until 2 p.m. The majority of fractures do not need reduction, and at present the patients are kept waiting through poor x-ray facilities and a shortage of nurses who can apply plasters. Patients are given appointments for all attendances after their first.

The Basic Factor.—The basic factor in this system, as well as in the other systems mentioned, is the number of patients that can be seen each hour by the medical staff concerned. The staff in this clinic is one surgeon.

Size of the Appointments Groups.—The standard aimed at is to see each patient within half an hour of arrival; therefore the clinic has been divided into half-hourly groups. The optimum size for each group was found to be fifteen, and the maximum number that could be seen in half an hour was twenty. The plastic quality provided by working at a rate well within the maximum is essential. It means that up to five unexpected patients can be seen every half-hour without upsetting the system. A more exact and ambitious system is too brittle to survive in practice. Too much insistence cannot be placed on plasticity as the fundamental quality of success. The first appointment group is arranged for 9.15 a.m. and the others follow at half-hourly intervals.

Method of Giving Appointments.—Of several methods only one was efficient. The clerk must visit each patient with the surgeon and give the appointment under his supervision. The time, day, and date must all be written on the patient's appointments card. The patients' ingenuity destroyed all the other methods Gaps will occur between the appointments groups, wasting the time of the whole staff (surgical, nursing, and massage), unless the rule of filling all the 9.15 appointments before any are given for the later groups is strictly kept. This rule is waived only on the plea of serious transport difficulties—i.e., a patient living more than thirty miles away may be given an appointment for 10.45 even though earlier times are unfilled.

Table showing Fracture Statistics for 1938 (2,573 Cases)

Radio-carpal dislocation		1

Documentation of Appointments.—A very simple method is employed. It is exactly the same as that used in a theatre-booking-office. In the appointments book a large square divided into twenty small squares is provided for each group, and when an appointment is made one of the small squares

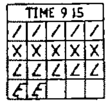

Diagram illustrating specimen from appointments book.

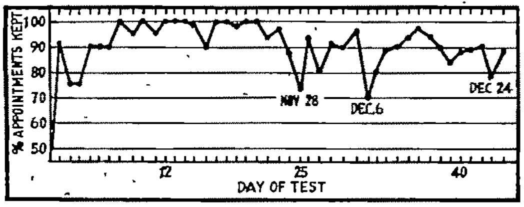
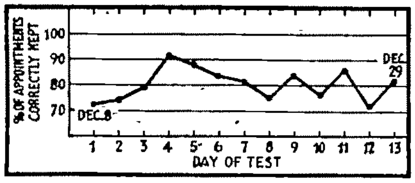
The first row shows the method of recording appointments. The second row shows how they are cross-checked when correctly kept. The third row shows how they are converted into Ls if the patient is late. The fourth row shows how an E is put into one of the five blank squares if the patient attends without an appointment is crossed off. Usually only fifteen of the twenty small squares are crossed off in each group (see above). If the appointment is correctly kept it is cross-checked and the patient complimented. Any arrival more than half an hour after the appointed time is considered as late and the corresponding small square is marked L. Such patients must be reprimanded when necessary. Patients who arrive without an appointment for that date are recorded in one of the five blank squares—i.e., E (extra). The accompanying diagram shows a specimen from the appointments book. In a clinic of this type there is no need to record either the names or the serial numbers of the patients. It wastes both clerks and time. Graph I shows that the great majority of the patients attend regularly if not punctually. The more elaborate system of recording names and numbers, as in the St. Thomas's method, is necessary, however, if the patients are to be followed up efficiently over a period of months after the conclusion of their active treatment.

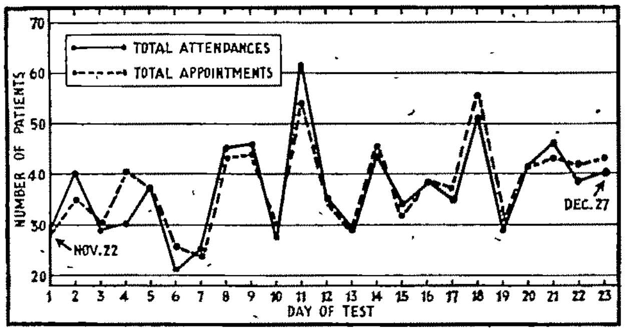


GRAPH I.—Relation of total appointments made to total appointments kept (irrespective of punctuality).

Punctuality of Patients.—Graph I demonstrates that on only five days out of forty-four did the percentage of appointments kept fall below 80%, and it never fell below 70%. Graph II demonstrates that, during fourteen days of testing, the number of appointments correctly kept was between 72% and 91%. Graph III shows in real numbers the close relation between the total number of appointments given and the total number of patients who attended. It shows how the number of patients who attend without appointments or on the wrong day almost exactly equals the number of appointments broken. Therefore the scheme as a whole is undisturbed. To check the patients' punctuality the appointments card is placed on the top of the notes for inspection by the surgeon.



GRAPH II.—Percentage of appointments correctly kept.



GRAPH III.—Relation of total appointments made to total attendances (from *all* sources) in real numbers.

Causes of Failure.—Nothing has been said on this subject in the descriptions of the schemes which I have examined. The problems that have presented themselves in this fracture clinic are grouped under five headings:

1. *No Appointment given to the Patient before leaving the Clinic.*—Due to neglect on the part of the medical and nursing staff; the patients' failing to call at the office to get an appointment on their way out; the office being shut (lunch-time, week-ends, and after 5 p.m. daily).
2. *Appointments given, but the Patients Misunderstanding Instructions.*—Due to deafness and mental deficiency or losing their appointment card.
3. *The Wrong Appointment Time given by Careless Medical Staff or Unauthorized Persons* (massage department, porters, women cleaners, other patients, and outside doctors).
4. *A Fresh Appointment not obtained at Each Attendance.*—This proved to be a real difficulty. The patients thought that once they had been given an appointment they were always to attend at that time on their subsequent visits.
5. A correct appointment given, but the patient arriving more than half an hour late or attending on the wrong day.

Local Facilities.—These vary considerably in each hospital, and it is therefore a waste of space to describe in detail the actual arrangements of this fracture clinic.

Additional Problems

New Patients.—The method which has been described proves that old patients can be organized in a practicable appointments scheme. The inclusion of new patients in the scheme, an attempt which Howarth (1939) did not make, might be achieved through the institution of an appointments office with a special telephone line and number which would be staffed by a clerk from 8 a.m. to 10 p.m.: this system has been put into practice by the Royal Sheffield Infirmary and Hospital and the Jessop Hospital for Women at Sheffield, and also by University College Hospital, London. (I have been unable to discover whether these schemes worked efficiently.) The following figures demonstrate that it is well worth while organizing the old patients alone, as in the last two years 70% of the attendances at the orthopaedic out-patient department of this hospital were those of old patients, and the chief clerk of the general office assures me that 50% of the attendances at the general surgical and medical out-patients clinics are also those of old patients. He showed me the figures for a representative month—i.e., November, 1941—to substantiate his statement.

The Teaching of Students.—The teaching of students must, as Howarth recognized, be carried out by a person not required for the routine work of the clinic. It is impossible to evolve an efficient system based on personnel that might take three-quarters of an hour's teaching on one case and only five minutes on the next one. As urgent cases are not out-patients, the teaching material should be selected the previous week by those carrying out the routine work, and brought up at a pre-arranged time for the teacher to take his class.

Conclusions

It is a short-sighted hospital policy to sustain an inefficient and out-of-date system in regard to out-patients.

An appointments scheme is practicable at least for old patients.

The advantages of an efficient appointments system are obvious so far as the patients are concerned. They are also great for the medical personnel for the following reasons: (*a*) The reputation of the personnel of the hospital is increased by association with an efficient system. (*b*) It enables medical personnel to know almost exactly at what time they will start and finish their work: this enables them to plan their other work accordingly.

The punctuality, and the determination of the medical personnel to succeed, are the corner-stones of the system.

Any system which is to succeed in practice must be plastic enough to absorb the considerable irregularities imposed on it by human nature.

Teaching must be performed by medical personnel not carrying out the routine work of the out-patients.

A practical efficient hospital system will only be evolved through the efforts of the medical and administrative personnel of the hospitals concerned.

I wish to thank Prof. H. Platt and Mr. R. L. Newell for their help in the preparation and presentation of this paper.

Reports of Societies

WAR STRESS AND THE INCIDENCE OF NEUROSIS

The seventh annual medical conference of the Ex-Service Welfare Society, which was held on March 11 under the chairmanship of Lord HORDER, was attended by psychiatrists from all parts of the country and from the Services. The subject was "The Influence of War Stress on Neurosis and Psychosis in the Armed Forces, in Industry, and in the General Population." Lord Horder testified to the valuable work of the Society in dealing with men suffering from neurasthenia and mental breakdown, and referred to the Society's industrial centre at Leatherhead, where men were employed on a self-supporting basis.

Lieut.-Col. T. TENNENT of St. Andrew's Hospital, Northampton, said his experience did not bear out the common opinion that the incidence of neurosis in the civil population had not increased under war conditions. To judge from the admissions to the hospital of which he had charge, there were three peaks of increase in 1940, coinciding with the collapse of France and Belgium, the beginning of intensified air raids on this country, and at a later period when severe damage was done in areas where these people lived, although they themselves escaped physical injury. His Service experience was limited to women suffering from psychotic illness, over 20% of whom had had a previous history of such illness. Psychotic illness was in some cases manifested when a girl failed to adapt herself to Service conditions. A rather different point of view was put forward by Surg. Capt. DESMOND CURRAN, who said that the thing which had struck him was the small number of people who broke down even under severe strain. At one naval hospital 85% of cases of anxiety states were returned to duty within a few months. Selection for the Navy was largely self-selection, and the major cause of breakdown was regimentation and the restrictions of Service life, actual war action playing only a secondary part.

Fitting the Man to the Job

Brigadier J. R. REES said that in the Army a complete job analysis had been carried out with a view to adjusting the man to his specific task, and, although it was not perfect and was late in starting, it was working extremely satisfactorily, and men who had a neurotic tendency were able to give better service and to become less liable to breakdown. Many of these men were quite stable so long as they went on doing a job which they understood, but showed signs of breakdown when expected to assimilate new ideas or to increase the tempo of their activities. In view of the amount of prophylaxis which was undertaken, he did not believe that the pensions problem at the end of this war would be of anything like the dimensions of that at the end of the last; so many men of inadequate personality would have been previously sorted out from the employment point of view. Some 80% of the men who broke down under the stress of war went back to duty after a very short time; there remained the chronic neurotics, who would be a problem for Government agencies and voluntary societies after the war.

For the Royal Air Force, Air Commodore BURTON said that the larger incidence of such breakdown as there was occurred among the ground staff rather than among the flying crews. His information was that the men were standing up in a remarkable way to the stress to which they were exposed without developing nervous illness—a tribute, of course, to the methods of selection employed, with the elimination of the substandard and the non-adaptable. Of those who did develop neurosis, many had it "ready-made," so to speak, and the effect of service had little bearing on its origin.

Prediction and Prevention

A Canadian medical officer, Col. VAN NOSTRAND, said that the fact that Canada had no conscription for oversea service altered the whole picture of the health of Canadian Forces in England. He also noted that such nervous illness as did occur was less marked during the "blitz" period than during the long monotonous lulls.

Dr. P. R. BOLUS (Ministry of Pensions) said that in persistent cases it was evidently the pre-war make-up which determined the neurosis. He thought that the influence of war was not of itself causative, and this was supported by the fact that during the last war the suicide rate fell appreciably, and his impression was that it had fallen also during the present war. Dr. the Hon. W. MACLAY considered that one of the difficulties of these cases was the provision of incentives and motives for getting well. He described the manner of handling discharged cases under the schemes of the Army and of the Ministry of Labour.

Dr. J. H. MACDONALD said that the amount of neurosis was not anything like what had been expected. During air raids on Glasgow and Clydeside the reports showed almost an absence of civilian psychosis or neurosis. Lady BRISCOE also said that very few cases had occurred among the girls of the Land Army. Dr. C. P. BLACKER spoke of his interviews with a considerable number of medical officers of factories and their diverse opinions, as regards both present conditions and expectations as to what would happen on the transition from war to peace. They were unanimous, however, in the view that war industry was capable of assimilating quite a number of people who were in certain respects inadequate, but when the transition began large numbers might be thrown out of employment and the problem would then assume formidable proportions.

Anxiety States

Col. A. A. W. PETRIE said that war stress precipitated existing tendencies to neurosis and psychosis. The first obvious reaction in war was anxiety, and this largely followed upon family separation. Absence without leave was often traceable to the anxiety of the soldier concerning his home. The morale of the Army largely depended upon soldiers' families, and over-anxious wives were sometimes the cause of anxiety states in their husbands. Another possible cause of neurosis was the sedentary routine to which many A.R.P. workers were condemned. Trouble arose not only from the unwilling but from the over-willing, who suppressed details of their previous history, which would have debarred them from service or from certain service. He pleaded for rehabilitation centres under the Ministry of Health.

Air Commodore R. D. GILLESPIE spoke of the good effects of training, after which people did much better than, from their mentality, one would have expected. Dr. AUBREY LEWIS referred to the effect which a returned neurotic was likely to have upon his family, and urged that doctors and psychiatrists should have much more opportunity of advising with regard to the reintegration of people into social life. Surg. Cmdr. HENDERSON said that men suffering from these conditions should be neither returned to their unit nor discharged from the Services; there was need for some clinic organization capable of dealing with them. A plea for a considerable extension of psychiatric work in general hospitals was made by Dr. SLATER, who said that many neurotics became worse after they returned to civil life because they were unable to get adequate treatment.

At a dinner which concluded the conference Sir WALTER WOMERSLEY, Minister of Pensions, who was the chief guest, said that, while the Ministry was ready to grant pensions to men whose mental state made them totally unfit for employment, it was more concerned, in the men's own interests, with the treatment and after-care of those who could be restored to health, wholly or partially, and placed in employment.

ASTHMA IN CHILDHOOD

At a meeting of the Section for the Study of Disease in Children of the Royal Society of Medicine on Nov. 27 the subject for discussion was "Asthma in Childhood." It was opened by Sir ARTHUR HURST, whose address is printed in the opening pages of this week's *Journal*.

The Management of the Child

Dr. G. W. BRAY said that there were three types of asthma in children: the hereditary type, developing usually between the third and fourth years; the eczema prurigo-asthma syndrome, starting at about four months with eczema of the face; and the lung damage type, to which last the sexes were about equally susceptible, but brown-eyed children were affected more than blue-eyed. Usually adrenaline would relieve the acute attack. If from a careful history it was found that a child had an attack after eating a particular food, and the skin reaction also was significant, the particular protein should be removed from the diet or denatured by prolonged heat. The child should have his meals early in the day, his last meal several hours before retiring, and no food should be given at bedtime except possibly fruit juice. A glass of milk last thing at night was a cause of trouble. Cleaning of the child's room should be done by vacuum, and the child should not wear woollen vests. He had hardly ever seen a case sensitive to one allergen only.

Mr. James Crooks spoke of the part played by naso-pharyngeal infection. He was of opinion that disease in the upper respiratory passages might lead to asthma without the intervention of a second factor. The effect of allergens on the nasal mucosa of a sensitive subject was to cause great swelling of the mucous membrane and a mucoid discharge. If the effect only occurred at intervals the mucosa returned to normal, but if it was prolonged the swelling persisted, the oedematous membrane participated in the allergic response, and blockage of the sinuses took place. Inflammation in the sinuses appeared to be an ideal starting-point for the establishment of high sensitivity, thus preparing the ground for asthma. Infection in the nose and throat was not often the main or primary cause of asthmatic symptoms, though it much aggravated the asthmatic condition. He had not found that surgical treatment of an infected focus in the nose and throat caused an increase of asthmatic symptoms, but it might be wise to avoid an operation in the height of the hay-fever season. He indicated certain local measures for the treatment of allergic rhinitis, including nasal sprays or drops, tampons, and, best of all, the displacement treatment introduced by Proetz. Zinc ionization for hay-fever was also mentioned.

Simple Psychotherapy

Dr. C. H. Rogerson said that it was usual to find in a case in which a psychological basis was prominent that all physical measures had been taken before the patient was sent to the psychiatrist as the last resort. In a large majority of asthmatic cases the psychological treatment ought not to be given by a psychiatrist at all, but by the physician in charge. There was often an unusual quality in the relationship between the child and one or both parents in these cases. The asthmatic child tended to be a special personality, irritable and aggressive, with an intelligence above the average, also over-anxious and lacking self-confidence. An important connecting link between the psychological and the physical condition appeared to be tension. From a psychological point of view the asthmatic stood tension very badly; when free and relaxed he was able to resist far more harmful stimuli without developing an attack. Success in treatment might be due to the feeling of confidence which it gave. Very occasionally it might be necessary to remove the child from home permanently or, in a larger number of cases, for short periods.

In a brief reply Sir Arthur Hurst said that he accepted the three aspects of asthma—the allergic, the nasal (which was largely reflex), and the psychological—but not one was effective without the asthmatic diathesis. The important thing in the management of the child was to encourage it to live a normal life; nothing could be worse than for the child to be made to appear different from everybody else.

Since 1941 over 36,250 children under 15 have been immunized against diphtheria in the county districts of Northamptonshire. During that time only one of those children contracted the disease, and the attack was not fatal. On the other hand, among some 19,400 children in the same county districts who had not been immunized, there were 101 cases of diphtheria and 15 deaths. Out of 8,000 children under 5 who had been protected there was not a single case of diphtheria; while among 9,200 children under 5 who had not been immunized there were 36 cases and 11 deaths. Of children under the age of 5 in the county districts of Northants, including Kettering borough, 46% have been immunized, and 74% of those between 5 and 15. The percentage for all ages up to 15 is 65. The Ministry of Health's campaign aims at securing the immunization of at least 75% of the child population of England and Wales.

Correspondence

Amnioplastin as Absorbable Tissue Isolator

Sir,—When, early in 1940, Chao, Humphreys, and Penfield reported the results of experimental work with prepared amniotic membrane (*Journal*, 1940, **1**, 517) it appeared that at long last a difficult surgical problem had been solved. A substance which, when interposed between a damaged structure and its surroundings, would absorb while the damaged structure was healing and so isolate it by preventing it from adhering to its surroundings had long been desired. So hopeful were the early reports of amnioplastin, as the Toronto workers called the prepared amnion, that in common with others I was not long in testing the claims made for it.

On clinical grounds some success was secured which appeared to justify the publication of experience with it in the treatment of peripheral nerve injuries (*Journal*, 1941, **1**, 587). In several cases, after freeing damaged and adherent nerves, early return of function followed its use, but such improvement may have been dependent upon factors other than the amnioplastin, and the following comment was made: "It remains for the future to determine whether the late results of these peripheral cases are equally good and for an opportunity to occur by which we may ascertain from the condition of the operation field whether neural isolation persists and whether the membrane is absorbed as completely in man as in experimental animals."

Such an opportunity has now occurred on two occasions, in each of which it has been possible to re-examine the operation field, in the one case seven months, in the other five weeks, after the amnioplastin had been introduced. Both patients had gunshot injuries of the median nerve with adherent fusiform swelling of its trunk above the elbow, and because of failure to improve or obtain more than temporary relief from pain following amnioplastin isolation were reoperated upon, the neuromas being excised and end-to-end suture performed. In neither case was there any trace of the membrane to be seen, but in each dense adhesions were present between the nerve trunk and the surrounding tissues, from adhesion to which it had been hoped to isolate the nerve by the interposition of the membrane. The membrane had thus proved ineffective as an "isolator," and these cases would appear to supply a direct answer to the question raised in 1941; but further evidence is afforded by recent experimental work (Hicks, Trethewie, and William, *Austral. New Zeal. J. Surg.*, 1942, **11**, 268) which has also failed to verify the results claimed by the introducers of amnioplastin.

Thus it would appear that the claims made for amnioplastin have not been substantiated, and the highly promising outlook created by the early reports must give place to disappointment. The satisfactory isolating substance which will prevent adhesion and later absorb so as to leave the damaged but healed structure free from its surroundings is still to be found. Search for it is very well worth while. When it is discovered it will be of inestimable value in surgical practice.—I am, etc.,

Lambert Rogers.

Tuberculosis in Wartime

Sir,—The report on tuberculosis in wartime by the Medical Research Council's Committee, reviewed in the *Journal* of Oct. 10, 1942 (p. 436), emphasizes the serious shortage of facilities for the in-patient treatment of pulmonary tuberculosis which exists in Great Britain to-day. The reasons for this shortage are ably analysed in the report, and suggestions are made which may in time, if implemented, go far to remedy an unhappy situation. None the less, consideration of the suggested methods of providing, equipping, and staffing more beds shows that during the war it may well be found to be a difficult and slow process. The need for more facilities, in fact, is likely to persist for some time.

At present many patients, both from the civil population and from the Services, await sanatorium or hospital vacancies in their homes for periods which are quite frequently of several months' duration. During this time they are rarely under adequate medical supervision, a considerable proportion disseminate infection, and their condition often deteriorates, with the consequences that fresh cases are produced, individual prognosis becomes worse, and a longer period of in-patient treatment is subsequently required for efficient therapy.

One method, not discussed in the report mentioned, whereby the available number of beds in special hospitals and sanatoria may in effect be increased lies in a greater use of active therapeutic measures. Thus, if within the various special institutions set aside for the treatment of this disease collapse therapy in all its forms were more extensively undertaken, it would be possible considerably to shorten the duration of the average period of in-patient treatment. For example, patients admitted with relatively early disease might, without undue delay, provided that medical contraindications did not exist, have artificial pneumothorax therapy started, and after a short period return to civil life, continuing to attend for supervision and refills at local hospitals or dispensaries where appropriate facilities existed. In this way the pressure upon the sanatoria would be to some extent relieved, and the work of managing these cases transferred in part to dispensaries, the out-patient departments of hospitals, and occasionally to specially qualified doctors, in all of which instances, as compared with sanatoria, the staff, and particularly the female staff, needed to handle these patients is proportionately much smaller.

The combination of collapse therapy and sanatorium treatment is, of course, essential in many cases and is very desirable in still more. Until we can attain that ideal, however, it is better that selected patients should receive some therapy such as the above and the remainder in-patient treatment according to their needs than that all patients should remain virtually untreated for considerable periods in their own homes. Experience has shown in the U.S.A. and elsewhere that collapse therapy in ambulant patients is practicable and satisfactory from the patient's point of view and from that of public health. Accordingly, it is suggested that as a wartime emergency measure it might be used to a greater extent in this country until the shortage in sanatorium accommodation is made good.—I am, etc.,

W. D. W. BROOKS.

Bacteriophage Treatment of Bacillary Dysentery

SIR,—Surg. Cmdr. D. C. Wilson (July 18, 1942, p. 81) makes certain remarks on my article (June 13, p. 719) which I trust I may be allowed to reply to.

He makes the point that my figures deal only with death rates (which of course was all I set out to deal with) and not with duration of illness; and on the strength of this he states that the aim of all three Services is "to return a fit patient to duty at the earliest possible moment." Many Alexandrian onlookers, who sometimes see more of the game than the players, will be astonished at this gratuitous statement. Actually my theme has always been: there is no need for other than a minimum of Service dysenteries ever reaching hospital. This latter occurs usually when they have passed to the stage named by me "neglected dysentery" (*Journal*, 1941, **2**, 280), with resulting greater incapacity and need for longer sick and convalescent leave than if their dysenteries had never been allowed to develop into full-blown attacks. *Preventive development* of dysentery from pre-dysentery phases like "Gyppy tummy" could, I feel every confidence in asserting from civil experience, be easily achieved by making available adequate supplies of good phage preparations at all advanced Navy, Army, and Air Force units, for administration on the first appearance of intestinal upsets of a pre-dysentery character. Has Cmdr. Wilson not, in his own words, confirmed that "civilians in Alexandria are so 'phage-minded' that to my knowledge they treat themselves with bacteriophage on the slightest suspicion of 'Gyppy tummy'"? Therefore I think I am in a position to set his mind at ease regarding "duration of illness," feeling sure that the adoption of a sound phage policy such as outlined could effect more in the way of improving this aspect of the situation than whatever measures may hitherto have been at work.

Cmdr. Wilson refers to a trial, in which he took part, of phage therapy in a small number of dysentery cases in an Alexandria Service hospital, from which he concludes that there was not enough "variation in hospital time" between the phage-treated and the control groups "to justify the continuation of the bacteriophage treatment." The inference here is, of course, that phage did not live up to what was expected of it, and proved no better than "the then standard treatment of sodium sulphate and fluids." The inference is misleading, in that the experiment, in my estimation, was doomed to failure from the start; and the description given of it deals with no more than the opening act—curtain raiser might be a juster term—since, Cmdr. Wilson will recall, the performance was stopped by superior military orders before it had got properly under way. This helps to explain the challenge of my letter in the *Journal*, which challenge still remains open.

Finally, Cmdr. Wilson reports that by the introduction of sulphaguanidine in the spring of 1941 a reduction in the duration of illness to 11 days from the onset was achieved, which result "appeared to make the further trial of bacteriophage superfluous." I hope Cmdr. Wilson will forgive me disillusioning him, but the facts are that statistical analysis of the recent authoritative Army figures of Cols. N. Hamilton Fairley and J. S. K. Boyd (*Lancet*, 1942, **1**, 20) and of my own figures of 13 years ago (*Lancet*, 1929, **2**, 273) reveals that sulphaguanidine presents no advantage whatsoever over phage in its rate of cure of the acute disease. Moreover, can the sulphonamides be administered with impunity to provide like "preventive development" of full-blown dysentery that phage can? If so, why then as to-day's "favourite" are they not made available at once, and used, where they are most needed—the front line of all three fighting Services?—I am, etc.,

ARTHUR COMPTON.
Director of Laboratory Service, Alexandria Municipality

Prescription of Lenses

SIR,—The attention of the Council of British Ophthalmologists has been drawn to the difficulty which the Services and the Ministry of Health are experiencing in obtaining spectacle lenses to supply their urgent needs, and it has been suggested that the situation could be helped by a simplification of the prescriptions supplied by civilian ophthalmic surgeons. The Council has considered the question and makes the following recommendations:

1. That the prescribing of lens powers in steps less than 0.25 D (which is to say, lens powers commonly referred to as "eighth sights"—e.g., 0.87 D) be discontinued.
2. That the prescribing of prisms be reduced to a minimum.
3. That in the higher ranges, say above 4 dioptres, the prescribing of lens powers in steps less than 0.5 D be reduced to a minimum.

The above recommendations were adopted by the Army some time ago, and the Council is assured that their wide adoption in civilian practice would materially aid the situation.—I am, etc.,

FRANK W. LAW,
London, W.1 Honorary Secretary, Council of British Ophthalmologists

Weil's Disease

SIR,—Dr. J. C. Broom's letter (March 6, p. 300) deals adequately with points raised by Dr. K. Blum in a previous issue, but I feel that further comment may not be out of place.

Just as poliomyelitis without or before the onset of paralysis is unlikely to be diagnosed except during an epidemic, so is Weil's disease without jaundice unlikely to be recognized except under special circumstances, as when illness follows immersion in water known to be infected with the causative leptospira. Under these circumstances it is clear that there is little scope for serum therapy, which, to be effective, must be instituted before the onset of jaundice. On the other hand, Weil's disease with jaundice presents a characteristic picture, so that diagnosis can usually be made on clinical grounds, serological investigation later producing the necessary confirmation. There have already been several adequate descriptions of this clinical picture, but it may be of help to summarize the outstanding features on which diagnosis rests: (1) History of partial or complete immersion in water which may be contaminated with rat urine. (2) Sudden onset of illness, with shivering, vomiting, muscular pains, and persistent headache. (3) Onset of jaundice on or near the fifth day of the illness. (4) Polymorphonuclear leucocytosis; this differentiates Weil's disease from infective hepatitis (catarrhal jaundice). (5) Uraemia with low blood pressure early in the illness; the association of renal with hepatic damage renders Weil's disease one of the few conditions in which intense jaundice is associated with a high blood urea.

Since the outbreak of war I have seen many soldiers with jaundice, but in only one has the clinical picture suggested Weil's disease. This case was so typical as to leave little room for doubt, and serological investigation by Dr. Broom confirmed the diagnosis.—I am, etc.,

GEORGE DAVISON.

SIR,—The diagnosis between Weil's disease and infective hepatitis is often difficult, and it is true, as Dr. J. C. Broom points out (March 6, p. 300), that the leucocyte count may help in assessing the evidence. Probably consideration for space caused him to be rather more dogmatic than the facts warrant. Middleton and McFadzean (*Glasg. med. J.*, 1938, **130,** 173) pointed out that in the leptospiral infection the alleged leucocytosis is inconstant in different patients, and in the same patient at different times.

As an instance of the difficulties, may I quote the case of a farmer in this neighbourhood who, during an epidemic of infective hepatitis, died of leptospiral jaundice, the diagnosis being posthumously established serologically, although he had a leucopenia. Twelve months later his son on the same farm fell severely ill with jaundice from which he recovered, and which, in the absence of leucocytosis and with a negative result from his serum, one assumes to have been infective hepatitis.—I am, etc.,

Beaminster R. E. HOPE SIMPSON.

Abortus Fever

SIR,—The recent references to abortus fever have particularly interested me as I have within the last six months had two cases of *Br. abortus* infection in my private practice. The incidence of abortus fever, as Dr. J. Landess Horne (March 6, p. 299) remarks, is not only probably much higher than is generally believed but—and here is the important point—is almost certain to increase as a result of the policy of the Ministry of Agriculture of vaccinating non-pregnant cattle with living cultures of *Br. abortus.* Cattle so treated are given increased protection against the risk of abortion although at the same time their milk is rendered more dangerous for human consumption in the raw state. Apparently the Ministry of Agriculture is only concerned with the quantity and not with the quality of the milk produced, the latter being the concern of the Ministry of Food.

That this anomalous position should exist is an example of departmentalism at its worst. The policy of the Ministry of Agriculture can be justified *only* by the Ministry of Food coming promptly into line and introducing compulsory pasteurization.—I am, etc.,

Birmingham. ALASDAIR McI. SMITH.

The Outbreak of Small-pox in Swindon

SIR,—With regard to the article by Dr. C. Killick Millard (March 6, p. 288) it might be of interest to state what happened in Swindon during a small outbreak of small-pox connected with the infected ship which produced the Glasgow cases.

A child from the infected ship arrived in Swindon on June 1, 1942. His vaccination, performed on May 29, was unsuccessful. He was kept under daily supervision, developed small-pox on June 12, and was removed to hospital the same day. (Case 1.) A known contact of Case 1 developed mild small-pox on June 26, despite successful vaccination which was performed on June 14. (Case 2.)

On June 26 I was asked to see a man who lived in the same street as Case 1, but who, even after the most exhaustive investigations, did not show any contact with the first case. He was suffering from severe small-pox and the rash was well out when I saw him. (Case 3.) This man had travelled about the town on June 24, visiting shops and a doctor's surgery. He had also worked in a large factory five days before I saw him, when he must have been well in the incubation period of the disease. It would have been impossible to trace and supervise all the contacts of this man, and so the following steps were taken: (*a*) All known contacts, direct and indirect, were kept under supervision and vaccinated. (*b*) As it was not known who else in the community had been contacts of this man, and as it seemed likely that further cases would occur following contact with him, all the public were considered as "contacts," and were exhorted to be vaccinated. About 30,000 vaccinations were performed. There were no further cases.

My experience of small-pox is limited, but when it was found that this disease could strike at a distance, I did not see what else I could do, except take every possible means at my command to combat the spread. Dr. Killick Millard himself suggests that aerial spread is possible. It seemed to me that one should supervise and vaccinate all known contacts, and also try to build up a cordon round the case. "Mass vaccination" in Swindon only commenced after the three cases had been in contact with many persons, and if vaccination of the contacts, known and unknown, was not the effective means of preventing the spread, I should like to know what was, unless—and here I make a suggestion with some diffidence—there are some outbreaks of small-pox which are self-limiting and die out of their own accord.

Finally, after very serious consideration, I must say that given a similar situation again I would feel obliged to act in the same way.—I am, etc.,

LLYWELYN ROBERTS,
Medical Officer of Health, Borough of Swindon.

Generalized Vaccinia and Vaccination

SIR,—I was very interested in the article on generalized vaccinia by Dr. A. A. Jubb (Jan. 23, p. 91), and was not aware that it was of such rare occurrence. On Nov. 6 last year I did a primary vaccination on a soldier 18 years old which resulted in a normal vaccination. On Nov. 29 he reported sick on account of a rash, and on examination he was found to have a papular and vesicular rash on his neck, body, and limbs; there were also vesicles on the soft palate and mucous membrane of the mouth. He stated that he had had the rash for three days and that he felt quite well apart from a certain amount of irritation. He was put to bed and observed for a week, and the vesicles gradually turned into pustules, which subsequently dried up and disappeared. He never felt ill at any time, and his temperature only once rose above normal. The picture resembled that of the illustration in Malcolm Morris's *Diseases of the Skin,* 1903, except that the lesions were not so large. The case was seen by several medical officers, including two consultants, and none of them had seen a case before.

In the last seven years some 20,000 vaccinations have been performed in this station, and with the exception of the case referred to above the results have been entirely free from any but the most trivial complications. The method adopted, which has produced from 90 to 99% successful results and which can be done at the rate of 500 to 600 per hour with a good team, is as follows. The arm is cleaned with spirit on cotton-wool and is not rubbed, as rubbing causes irritation of the skin and is liable to spread the vaccination. A domestic bodkin is dipped in the ampoule of lymph and with the thick end a thin line, about half an inch long, is painted on the upper deltoid. An ordinary sewing needle about two and a half inches long is then drawn through the lymph with a light stroke. The stroke should just leave a thin white line where the epithelium has been disturbed, and there should be no bleeding. A piece of elastoplast about the size of a postage stamp is then fixed over the vaccination, and is left on until it drops off. The bodkin is sterilized by flaming before commencing and the needle is passed through the flame between each vaccination. There is no necessity to wait for the spirit to dry before applying the lymph, and the plaster can be fixed to the arm before the lymph has dried, thereby saving much time.—I am, etc.,

C. SCAIFE,
Home Forces Lieut.-Col., R.P. (Temp. Major, R.A.M.C.).

Subclinical Vitamin A Deficiency

SIR,—If I do not waste too much of your valuable space, may I be permitted to make a few comments in connexion with the article by Major R. E. Wright (Dec. 19, 1942, p. 723).

The cutaneous manifestations of vitamin A deficiencies are well-known alterations of the skin, and there is no need to enter into further discussion. There appears to be, however, a good deal of controversy as to what constitutes a subclinical vitamin A deficiency, or, as I have referred to this syndrome, hypovitaminosis A (*Chin. med. J.*, 1936, **50,** 945), and what is the associated earliest sign. Referring briefly, "the earliest and most common sign, the smokiness of the conjunctiva," is emphasized by Wright. I would like to remark that in our cases observed we were unable to make a similar statement. Moreover, in a series of cases followed up for a long period (six to eight months), "none developed xerophthalmia, keratomalacia, or pigmentation of the conjunctiva." On the other hand, a slate-coloured, dry, easily scaly integument was almost a uniform stigma. It should undoubtedly be considered that deficient intake or utilization of vitamin A does not follow a strict pattern in its clinical manifestations, more especially in relation to ocular symptoms.—I am, etc.,

FREDERICK REISS,
Department of Dermatology, Society of the New York Hospital.

War Neuroses

SIR,—I have read with much pleasure the letter by Sir Arthur Hurst (March 6, p. 299), especially as I had the privilege through the hospitality of Sir Arthur and Lady Hurst to spend a few days at the Seale Hayne Military Hospital in the war of 1914-18. There I was greatly impressed by the rapid cures obtained in many of the functional nervous disorders by simple psychotherapy in the form of explanation, persuasion, and re-education. At the present time there seems to be a tendency to the revival of psycho-analysis, but I trust that those who practise such analysis will keep alive to the dangers of over self-inspection and of living in the world of feelings and fancies. We may admit that the study of the instincts and their unconscious role is necessary and valuable, but we must not forget to emphasize the importance of the education of the will in the conscious life.

Meanwhile, I wish to congratulate Sir Arthur Hurst on his able investigations extending over many years in the causes and treatment of the neuroses, both those occurring in civilians and in those who have been exposed to the perils of this agonizing war.—I am, etc.,

Chinley JUDSON S. BURY.

Surgery of Tendons

SIR,—On reading over your interesting annotation (March 13, p. 325) I was surprised to notice your statement that "very satisfactory results follow the repair of most tendons." After the extensive experience in traumatic surgery which I have had in Stoke-on-Trent for the last eleven years, I should be inclined to say the exact opposite. I seldom obtain a perfect result after the suture of a divided tendon, whether primary or secondary. Bad results are common after suture of both flexors and extensors, though, admittedly, they are worse in the case of the former. In the case of the latter, although good union can be obtained, this is almost always accompanied by shortening, causing permanent limitation of flexion.

I should like to make it clear that I am not speaking of the results obtained by house-surgeons, but of those obtained by myself after the most careful suture under what I believe to be the best conditions. I should very much like to know what results obtained by house-surgeons, but of those obtained by ence of tendon suture.—I am, etc.,

Stoke-on-Trent PAUL BERNARD ROTH.

Coarctation

SIR,—I was interested in Dr. C. W. Walker's account (Feb. 13, p. 190) of labour in a case of congenital coarctation of the aorta in a woman of 31, but would like to know a little more definitely on what he bases his diagnosis of coarctation. He merely states that "she was diagnosed at the age of 20 as a case of congenital coarctation." If coarctation is congenital the child usually dies at or soon after birth; if acquired it is due to infiltration into the vessel wall of ductus arteriosus fibres. This case, if really one of coarctation, may have been either, as the girl apparently enjoyed good health till the age of 8. If it was congenital she ought to have shown some signs and symptoms before that age, and if it was acquired she would have to have an enormous and extensive scheme of collateral circulation to supply the aorta with blood beyond the constriction, via a network including the internal mammary, posterior intercostal, phrenic, superior and inferior epigastric, inferior thyroid, posterior intercostal, transverse cervical, and other arteries. It would be interesting to know how all this could be ascertained without a necropsy, happily not needed in this case.

The ductus arteriosus in foetal life connects the descending aortic arch with the left pulmonary artery, and acts as a blood carrier between the two. After birth it should become obliterated, and is called the ligamentum arteriosum. The left subclavian artery comes off the aorta lower down the vessel, and, of course, persists. The short space between these two is slightly narrowed, and is called the "isthmus," and it is in this space that the rare stenotic condition known as "coarctation" is met with. In support of the diagnosis we have given us in the article that: (1) she had fainting fits at and from the age of 8; (2) she was incapable of exertion; and the following at the age of 31: (3) the heart was very much enlarged to the left; (4) a harsh systolic murmur in 2nd and 3rd intercostal spaces; (5) the blood pressure was 210/100; (6) marked arterial pulsation noted above the clavicles. Of these one would say that (4) is the only item in favour of the diagnosis. Common sense would seem to dictate that the blood pressure distal to the constriction would be low, whereas a hyperpiesis is present. As to (6), I have more than once noted largish pulsating lumps in the supraclavicular areas of hyperpietics, generally on the right side, due to the raising of the aortic arch in this condition.

It would be interesting if Dr. Walker could allow himself time to elucidate further the evidence on which he erects so rare and formidable a superstructure as "coarctation."—I am, etc.,

Stowmarket. H. S. GASKELL.

Sterilization of Dry Powders

SIR,—In recent numbers of the *Journal* which have reached this country I notice there has been some considerable correspondence upon the most satisfactory method of sterilizing such powders as sulphathiazole for use in controlling or preventing sepsis in surgical wounds. It appears to be generally admitted that moist heat solidifies these powders and renders them unfit for insufflation into a wound. During the last year I have made a practice of powdering each of my thoracoplasty wounds with 5 grammes of sulphathiazole, which is spread liberally over all the exposed tissues before suture of the wound is undertaken.

The sulphathiazole is weighed out into small glass bottles, which are closed with metal screw caps. Each of these screw caps is lined with a circle of waxed paper, which fits tightly over the mouth of the bottle and efficiently prevents the entrance of steam. The bottles are sterilized in a steam disinfector at a temperature of about 245° F. for one hour. During the last year the 85 consecutive thoracoplasty operations in which this technique was employed all healed by primary intention, there being no secondary infection in any wound with the exception of one case, where one skin stitch had to be removed on about the fourth day because of a little stickiness.

Before sulphathiazole was used approximately 8% of wounds showed gross infection, while another 15% showed some measure of minor infection requiring the removal of one or more stitches and the use of antiseptic dressings. It would appear that the method of sterilizing outlined above is entirely satisfactory for sulphathiazole, but I am not prepared to speak for the other drugs of the series, as I have not so far used any of them in this manner.—I am, etc.,

RICHARD A. S. CORY,
Senior Medical Officer.
King George V Jubilee Memorial Sanatorium, Jamaica.

Histamine and Insulin in Erythematous Eczema

SIR,—A woman aged 42 has been under my care suffering from melancholia, for which she has been treated with subcutaneous injections of histamine 1 mg. and insulin 5 units three times weekly for several months. She also suffered from erythematous eczema for more than ten years, her face, neck, forearms, and hands becoming red, swollen, and oedematous. From time to time cracks and fissures appeared on her mouth, neck, wrists, and fingers, and much care was necessary to promote their healing. During all these years she was never quite free from this condition; her life was a burden to herself and her appearance repulsive to others. Since histamine produces dilatation of the cutaneous blood vessels, and particularly those of the face and hands, each injection caused a temporary increase in the blood supply to the affected areas, and after a few weeks' treatment they began to improve. In three months the patient was clear of eczema, but the injections were continued for psychiatric reasons for another nine months before they were gradually discontinued. Since then any tendency towards recrudescence of the cutaneous lesion has been controlled by a short course of injections. Unfortunately, histamine produces constitutional effects which make it advisable to keep the patient under supervision for three-quarters of an hour after each injection. Nevertheless, eczema may be so intractable and intolerable that this rather difficult and prolonged method of treatment may be justified in special cases.—I am, etc.,

Crowthorne, Berks JOHN STUART KNOX.

Freedom to Practise

SIR,—Dr. Lindsey Batten's outspoken letter (March 13, p. 328) was much needed. There must be many who share his views but who keep silence from dislike of controversy. This is perhaps not surprising in view of the intolerant attitude adopted by the supporters of a complete State Medical Service towards any criticism. To be unwilling to swallow the scheme entire is regarded as opposing "social security" and to be "mentally if not physically dead." However, having become inured to such retorts, I would suggest that if Dr. Batten's admirable plea is not supported by those who agree with him there is a real danger of judgment going by default. I was recently at a meeting of non-medical "planners," and was appalled at the fate they were preparing for us. They were, for example, anxious to limit our right to practise to "licensed premises"—i.e., health centres. To resent this limitation is not to deny that such centres can have a useful function. But some patients still belong to the tribe of Nicodemus and prefer to seek counsel and healing in secret. To prevent their obtaining this from a qualified doctor simply plays into the hands of the quack. I once heard Mr. Bernard Shaw lecture on the advantages of not being on the *Medical Register*, to which it seems likely that he may be able to add a convincing addendum.

If we allow the organization of the profession to pass out of our hands we shall meet with short shrift from such planners. But even a medical hierarchy has its dangers, as you, Sir, have pointed out. Any extension of the rule against publication of a paper without permission of the officer in control of the service, which is already widely enforced, may be as disastrous to medical progress here as it has proved to be in Germany. Already some of my younger "Leftish" friends have been considerably disillusioned by autocratic medical superintendents.

I quite realize the attraction of a pensionable service in these days of excessive taxation and low rate of interest, because it is unlikely that doctors in the future will be able to save as much for their old age as a pension would yield. That changes are called for and are indeed inevitable is clear, but it is doubtful whether making us all civil servants will remedy all the defects in the present system, many of which are inherent in human nature. Gradual evolution is better than revolutionary changes in a profession which has been steadily advancing. Indeed, some changes must be gradual; thus I am told there is a serious and increasing shortage in the supply of dentists. Yet the planners call for an immediate extension of dental service. Do they realize it takes four years to train a dentist?

I wonder what sort of man will be attracted to the medical profession if and when it is cabined and confined in the ways suggested. In the long run a country gets the doctors it deserves. Having enjoyed the inestimable privilege of practising medicine under freer conditions, I do hope my successors will think not once but many times before selling their birthright for what may well prove to be a veritable mess of pottage.—I am, etc.,

London, W.1 W. LANGDON-BROWN.

SIR,—Writing, as I am, from a sick-bed, one seems to have a longer vision, and so I feel constrained to write a few lines once again upon this important subject. Every one of us must sympathize with all my friend, Dr. Lindsey W. Batten, said in his letter (March 13, p. 328). But we have to prepare for a future that we hope will be happier and better than the past, and think not in terms of the doctor but in those of the community. It is stated with authority that 95% of the public after the war will earn incomes that cannot provide adequately for private practice fees, with all its modern accessories, and they must be catered for under some such scheme as the Beveridge plan suggests. Well, why shouldn't they, and yet all the amenities Dr. Batten mentions be retained?

Certain provisos seem to be imperative. First, that the entire profession should place itself under the B.M.A. so that we can speak with one voice. Secondly, that the control of the medical side of the scheme shall be under medical and not lay supervision, while recognizing that, being a Government scheme, some control of the financial side by them is unavoidable. Thirdly, that the insurance is of such a nature that plenty of funds are available for adequate remuneration, instead of the huge profits being converted to the friendly societies, as at present in the panel system. Fourthly, that no obstacles shall be put in the way of ordinary practice being carried on for the 5% remainder of the population. Fifthly, that the salaries shall be adequate and in relation to each doctor's experience, qualifications, and standing.

In this way there is no reason why we should not retain our own patients, have complete freedom in our work, and we would also have access to all modern improvements, and have more freedom for study and recreation, thus becoming better doctors. For the sake of brevity I am leaving out all details which are controversial. Given good will on the part of Parliament, the public, and the profession, which last should, as I have pointed out in a previous letter, contain only the right type of man, some such scheme can and must be made workable if the public are all to get the full benefits of modern medicine.—I am, etc.,

Hampstead, N.W. HAROLD VAN PRAAGH

Scientific Freedom and Social Medicine

SIR,—Dr. Geoffrey Bourne (Feb. 20, p. 331) has put forward with vigour some of the pitfalls surrounding State Medical Service in so far as its contact with hospitals is concerned. Equally important are problems arising out of State control of the general practitioner, for it is clear that either a salaried service or extension of the panel system will engulf him in some system of control.

Within the past few years I have been told by three consultants, each from different London teaching hospitals, that the standard of the general practitioner in Britain to-day is extraordinarily high. It is my belief that this high standard is due to the sense of responsibility which his complete professional freedom enjoins upon him. To those who think that the absence of competition which a salaried service involves would tend to lower our standard, one may point to the modern tendency toward the union of practices into "firms," which removes the competitive element; yet the standard of such "firms" is, by common consent, above rather than below the average. Indeed, I would go so far as to say that competition is actually harmful in that it absorbs energy which could and should be more usefully spent.

If control there has to be, let those in control be not medical politicians but practical medical men answerable to the profession and to public opinion rather than to a Minister of State and Government Department. If the choice before the profession lies between a salaried service and extension of the panel system, I feel that the selection should be made by those who are coming rather than by we who are going. For my part, as one of the older men, so far from "preparing to sell the pass," as one of your correspondents expressed it, I can only say that the prospects of a salary, a pension, and a holiday with pay sound too good to be true.

If the medical provisions of the Beveridge report are to become a reality it is clear that the public are to receive not less but more medical attention than heretofore. On the other hand, it would seem certain that after this war the public will have less rather than more to spend upon doctors. I have long felt that much of the doctor's time is taken up in work which could as well be done by a more highly qualified nurse than exists to-day. I would suggest that if a higher diploma were instituted for nurses, including a primary examination in chemistry, physiology, and anatomy, conferring on the so qualified nurse a greater measure of responsibility and proportionately higher emoluments, then by this expedient a fuller use could be made of the doctor's time. Without entering into detail it is clear that the practice of such nurses could be ancillary to and co-operative with the practice of the doctor, who would then be freed to give his entire time to the more highly skilled work for which his long training has fitted him. By thus economizing the time of the doctor the increased medical facilities envisaged in the Beveridge report might be brought nearer to attainment without adding so much to the financial burden of the public.—I am, etc.,

Rye. MARTIN BUTTON.

SIR,—We have read with great interest and approval the article by Dr. Geoffrey Bourne. We have now had considerable experience, in the shape of Service medicine, of an autocratic medical system such as he describes. We agree that reorganization of the present medical system is essential in order that it may cope adequately with the increasing complexity of modern problems, but we feel most strongly that such reorganization ought to take place in accordance with the democratic principles so well outlined by Dr. Bourne.—We are, etc.,

C. J. ROOKE,
G. H. DAGLISH,
J. H. GRAVES,
Surg. Lieuts., R.N.V.R.

The B.M.A. and the Beveridge Report

SIR,—The proposals of the Beveridge report on medical services "is the ideal plan" (para. 437), but as an ideal plan needs ideal patients, doctors, and administration Sir William wisely says later in the same paragraph that "these proposals are provisional only." To write, as some of your correspondents do, as if the medical provisions of the Beveridge plan are sacrosanct is to fall into the errors of the supporters of the "idealist" League of Nations (of which I was one), which landed us in this present chaos. The report clearly realizes that patients are not yet ideal and suggests various checks on their ideal freedom. Health administration shows no sign of becoming ideal, or the Minister of Health—to take one instance—would be regarded as the natural champion of the rights and facilities of doctors instead of, as at present, more like their taskmaster because he is also their paymaster. Doctors cannot claim to be ideal either, and so most of them work better in an atmosphere of freedom instead of regulations.

It should surely be the business of the special Beveridge conference on March 31 to emphasize that great modifications of the ideal plan are necessary if it is to function satisfactorily in this imperfect world. Many points may be raised, but at least let us be practical and not carried away by a desire for doctrinaire consistency. And may I suggest that your numerous correspondents who seek to condemn the retention of private practice because it will "divide the loyalties" of doctors are really running away from life? Every doctor has multiple loyalties—to his patients, his profession, his family, his own health, and many others. Until a doctor has learned to put his patients first and to get the rest of his responsibilities into some sort of control he is not really fitted to advise his patients, who are little less distracted. To say that a doctor should only have one class of patient is a sad (and false) slur on the profession, for, in fact, panel patients are usually best treated by those doctors who have sufficient private patients to give them that sense of freedom without which their best work will never be done. And patients wish to be "private patients" mainly because they wish to be free of regulations too. Those who wish for State medicine can get it at the price of freedom or regimentation, but there is every reason why as many as possible should be encouraged to keep what freedom they have got.—I am, etc.,

Winsford, Cheshire. W. N. LEAK.

SIR,—Dr. J. Shackleton Bailey (Feb. 27, p. 266) asks, "If the whole resources of modern medicine are at the disposal of every man, woman, and child in the country, what else will the medical profession have to offer anyone at any price?" and then suggests that proviso (*b*) hangs on that question. Surely Dr. Shackleton Bailey confuses a standard of medical service with a standard of medical practice. To take a simple example, let us consider the case of a mother who wishes to have her child immunized against diphtheria. The child is immunized while otherwise in good health; therefore there is no reason why it should not be taken to the doctor's surgery. On the other hand, the mother may prefer to have the child immunized at home. Is the mother to be compelled to take the child to the doctor's surgery if she is willing to pay to have her child treated at home? Parallel instances of one standard of service with varying standards of practice could be multiplied a thousandfold.

Irrespective of the standard of service the standard of practice must be determined by the remuneration of the doctor. If the experience of the scale of remuneration under the Maternity Service (Scotland) Act, 1937, can be taken as a guide, the standard of practice in the future will not be comparable with the highest standard existing to-day. I would suggest that proviso (*b*) gives scope for a varying standard of practice without in any way necessitating varying standards of service. I would further suggest that the existing demand for varying standards of practice will not be eliminated by a national medical service.—I am, etc.,

Milngavie. DONALD MACDONALD.

Consultation between Government and Profession

SIR,—I have read with alarm amounting to consternation the letter on this subject from the Secretary of the Ministry of Health (March 20, p. 359). At the moment I am not concerned with the merits or demerits of a State Medical Service: that is a matter which must be decided by earnest and unbiased consultation between the profession and the Government and, I hope, representatives of the sick public. But I am concerned with the form of attack with which the liberty of the public and the profession has been assailed. For lack of a better expression it might be called "psychological infiltration," of which tactics I thought until to-day that Goebbels was the acknowledged master.

The sentence to which I take the greatest exception in the letter is: "I need not tell you that the establishment of a health service on the lines envisaged by the Government would constitute the greatest single step forward in public health in the history of this country," etc. By this sentence the Ministry has committed itself to a view and has endeavoured to "force" its view on the public by blandly presenting as an axiom, and therefore not open to argument, what is indeed only a hypothesis; and it has presented this—the whole crux of the matter—as an assumed fact without one iota of evidence having been taken on the subject. This sentence should have read: "I need not tell you that the establishment of a health service on the lines envisaged by the Government *might* constitute the greatest single step forward, *or backward*, in public health in the history of this country." The problem for investigation would then have become clear, as in fairness to the public it should be made clear.

If we are to arrive at the truth we must have facts; and no preconceived ideas or theories must be allowed to interfere with a diligent search for all the evidence of fact. The first question to settle, then, is: Would the population of Great Britain get better treatment through a State Medical Service than it could get without it? Many of those who, like myself, have studied on the spot problems of health in many countries will agree that the average man gets better medical and surgical treatment in this country than anywhere else in the world. That does not mean that a far better medical service than the present one might not be envisaged; but at least we already have one of the best if not the best. Until the problem has been settled by a study of *facts* no attempt should be made to discuss ways and means. The principle having been established it would become our duty to implement it; but our first duty is to establish the principle.—I am, etc.,

London, W 1. H. E. GRIFFITHS.

Future of Women in Medicine

SIR,—Young medical men and women students have much to gain by working together. War conditions have forced men and women to work together in the Services, in the factories, and in business and professional life as never before in the history of the British people. By so doing they are learning a new comradeship and a fresh appreciation of each other's points of view. It is a vast experiment, and as in all times of high testing some of the weaker ones will fall. It is curious that Dr. Calder (March 13, p 329) should at this time feel so strongly that medical men and women students should be strictly segregated. She seems sadly out of date in her views. Fifty years ago, when women had to fight pugnaciously for admission to the medical schools, they had to wear a masculine aggressive air or they would never have achieved recognition. They still must struggle hard to deserve important positions and high appointments, and so far with many notable exceptions they have not done so.

When women do specialize more and take the trouble to work for higher qualifications, I feel sure that, by common accord of men and women, medical work for which by virtue of their being women they are best fitted will be open to their particular talents. It is not by any means accepted "that women are the best people to administer to women and children." Children happen to be born both male and female in about equal proportions. It is true that some unsuitable women become medical students, but that applies equally to men, and both tend to be weeded out by the rigours of the long course of training.

Dr. Calder's objection to the teaching of birth control seems irrelevant to the main subject of her letter. She must look at past and prevailing social and economic conditions in order to discover the causes of the declining birth rate. If she knew anything about the work of birth control clinics she would appreciate that the reason for their establishment is to ennoble motherhood, not to degrade it. There is nothing dignified in a diseased woman bringing a sickly child into a poverty-stricken household. Dr. Calder would also discover at the clinic, if she could bring herself to enter the portals of such a woeful place, that there are a great many women to-day of child-bearing age who are longing for children, and who are, for reasons little understood or studied, apparently unfertile. Birth control clinics throughout the country have considerable evidence of this. Gloomy prophecy of racial extinction need not cause alarm and despondency if thoughtful men and women worked together to create a better world for the young people of the future.—I am, etc.,

Newcastle-upon-Tyne. DOROTHEA W. SINTON.

SIR,—I cannot let Dr. Jane Scott Calder's letter (March 13, p. 329) go by unchallenged. Fortunately, I do not believe there are many medical women or men who share her views. The only point on which I agree with her is that men and women are not identical. I would add that they are complementary to each other, and their work should also be complementary. To achieve this ideal the more men and women work together from their training onwards the better.

For my own part I was trained in a women's medical school, and at that time it probably offered the best all-round training in medicine for a woman, but I welcome the possibility of women being admitted to other medical schools previously open exclusively to men. It is more than a courteous gesture of recognition and encouragement; it is necessary progression. Since qualifying I have worked continuously with men doing similar work under the same conditions. I have found it stimulating and enjoyable. I have rarely found it necessary to fight for my rights as a woman, certainly not in the last ten years. I have learnt much from my male colleagues, and I hope I have had something to give in return.

I trust no one will ever seriously consider suggesting that medical women should revert to such a narrow-minded medieval status as that mapped out by Dr. Scott Calder. That women, in contradistinction to men, should adopt a uniform policy on such a subject as birth control seems to me to be ludicrous. Surely it is a subject of equal importance and interest to men as to women, and our policy must be that of the combined profession. Let us discuss these problems together, not from opposite camps.—I am, etc.,

Leicester. JOAN WALKER.

SIR,—The principles suggested in Dr. Jane Calder's letter for the future of women in medicine seem rather retrogressive in character, perhaps good for Dr. Garrett Anderson's day but not for 1943, when the realities of the profession as a whole are much more complicated. Were her salient "points" adopted we should "evermore come out by that same door wherein we went." In fact I think we would gradually be ejected by the back door. A woman doctor should simply walk forward hand in hand with her male colleagues, and her footsteps should be felt and not much heard. The fact that they are sometimes noisy and subversive is due to the admitted survival of the feminist type among us, and it is an acknowledged fact that this type is generally a product of the non-coeducational schools.

Women doctors do not *need* to "pine after the privileges of men"; they have them all, except, perhaps, adequate representation on important committees, and this is a difficult problem. The medical woman who gets to committee status is too often, unfortunately, the wrong type. She is generally a feminist who has concentrated solely on her own life and work and progress, and not on the world beyond—a bad mixer and diplomatist, not *persona grata* to her male committee colleagues, and thus not useful.

I do not ask space to challenge Dr. Calder's various suggestions, because other readers must, I am sure, be disposing of them in this correspondence.

The fault of 50% of medical women lies in that they allow themselves to become totally absorbed in the materialism of the job of being a doctor. They become introspective and introverted in outlook by their sheer enthusiasm. We should all make time to throw off the trammels of the medical mind occasionally—to go into the world beyond and experience relaxation and enjoyment. By so doing one understands one's patients—their psychological and physical reactions, and, above all, *their* point of view. The present medical education of women is all right, but it is within herself to become a good doctor.—I am, etc.,

London, W.1. LILIAN MURRAY.

Absenteeism in Industry

SIR,—As a general practitioner who, until the appointment of a whole-time medical officer, was part-time medical officer at a large factory may I endorse Dr. A. G. Eddison's plea (March 6, p. 303) for a schedule of terms to be used on certificates: in particular, one for that group of patients—and one is seeing an increasing number—where the trouble is due to prolonged periods of long hours of work often in artificial light, difficult transport to and from work, little or no chance of mental and physical recreation, and possibly domestic difficulties due to both husband and wife being in employment. These patients are not suffering from organic disease, and it is difficult to label them concisely on the usual certificate form without using terms such as "nervous debility." A letter to the industrial medical officer would no doubt solve the problem, but, unfortunately, we have little time to write letters nowadays.

Another type that is a difficult problem for the G.P. is the "round peg in the square hole"—the man or woman who for some reason cannot cope with the work that he or she is given. Unless some adjustment is made they will inevitably become absentees on some pretext or other. Here I am sure co-operation between G.P. and the industrial medical officer is essential, but this must be backed by sympathetic understanding on the part of the management. Certification is undoubtedly a major problem in general practice to-day, and I am sure that a schedule of terms would strengthen the hand of the G.P. and ease the difficulties of the industrial medical officer.—I am, etc.,

G. THOMPSON.

SIR,—Absenteeism is certainly a problem, as all will agree But quite apart from the ambiguous certificates to which Dr. A. G. Eddison (March 6, p. 303) refers, there are a large number of genuine but largely preventable cases about which something could and should be done. What about women called up and allotted to factories ten or fifteen miles from their homes, some of whom can only get to work by cycling there because there is no other means of transport? Others travel partly by cycle and partly by train. I know of some who have to leave home shortly after six o'clock to be in time for work at eight, and have been surprised at the number of these who do so without breakfast, taking a few sandwiches for midday and having nothing more until they reach home between 7 and 9 o'clock. They are usually too tired to eat after 10½ hours' work.

An obvious question is, "Why don't they use the canteens?" I have asked them many times, and the reply is nearly always the same: they "can't eat the food because it gives them indigestion." It is a common complaint that they cannot drink the tea provided "because it tastes so strong of soda" and upsets their stomachs, and they do not like to complain. Small wonder that after a few months of this some of them collapse from fatigue and are anaemic and undernourished. Their complaints may be justified or not; but there seems to be a certain unanimity about them. Absenteeism of this kind should be preventable. Such things do not occur in the Services or in commercial undertakings where welfare officers are in intimate relation with individual workers. The remedy would seem to lie in the closer liaison between an adequate welfare staff and the factory medical officer.

Factory inspectors should not be too lenient as regards working conditions merely because it is wartime. I have seen patients ill through working in a small shop where dope is used—which is not a dope shop although dope is used regularly all day long—without any enforcement of the customary regulations applying to such shops as regards ventilating fans. Only workers actually working with dope were issued with milk, while those engaged on other work within a few feet of them were issued with none. Is there any pretext for an inspector overlooking such a state of affairs? If welfare officers only knew the hardships which some women bear uncomplainingly before their day's work begins—and after it ends—but which prejudices their physical efficiency and consequent output, they might be able to advise and improve the conditions. It is equally important to ensure that meals served in canteens are well cooked and served in an appetizing manner at a reasonable price.

Getting down to "brass tacks," welfare officers and factory medical officers are employed as "money-savers," and by preventing or abolishing conditions which lead to absenteeism they should more than pay for themselves by keeping workers happy and efficient.—I am, etc.,

Brookwood, Surrey. H. M. STANLEY TURNER.

Private Fees of Salaried Medical Officers

SIR,—I believe that the majority of the medical profession would support Mr. T. W. Mimpriss in his contention (Feb. 20, p. 234) that medical officers should be allowed to retain fees for insurance reports, etc. It appears, however, that he is wrong in assuming that the Ministry of Health would also support this contention. On inquiry I am told that there is a Ministry regulation which forbids the acceptance of such fees by whole-time salaried officers. This is particularly interesting in view of the fact that whole-time salaried officers who are examiners are permitted to retain their examining fees, whereas the lower-salaried junior medical officers may not officially retain their fees for insurance reports. It is difficult to see that this arrangement is a fair one.

The circumstances in the two cases seem to be the same; each is doing work outside his routine medical duties, but in one case he may retain his fees, in the other case he may not. The only difference between the two is that, whereas junior medical officers do not take time off to produce their insurance reports, the senior medical officers take up to a week off for their examining duties. Perhaps there is a rational explanation for this rather confusing situation, but in any case, here surely is a situation which might be investigated by the B.M.A. with some hopes of an equitable conclusion.—I am, etc.,

Chertsey. J. H. PENROSE.

Venereal Diseases

SIR,—The constantly reiterated slogan, "This is an entirely medical matter," has perhaps more than anything else hindered the campaign against V.D. Let me give one example. At the end of the last war, in one of our Armies of Occupation, in spite of all medical measures the V.D. rate was so high that the military authorities at last agreed to allow the direct "moral" approach to be tried. The effect was remarkable. There was a dramatic decline in the number of infections, and within a few weeks the whole situation had changed. (The exact figures are on record, and I would gladly furnish Mr. Chartres with a copy of them.) This was brought about by a great Christian man, himself a V.D. specialist, who talked to the troops not as a doctor but as the best sort of father would talk to his sons.

Unfortunately, evidence—and I stress the fact that it is *evidence,* not pious opinion or wishful thinking—of this kind appears to be ignored by the authorities. At the very beginning of the present war a deputation, which included some of the most distinguished medical men in the country, went to the War Office to urge that in dealing with the problem of V.D. the lessons learnt at the cost of so much disability and waste of man-power should be given full weight and value. The deputation was coldly received, and its proposals were rejected. I was told that "this was an entirely medical matter" and that recent advances in prophylaxis and treatment would prevent the recurrence of the serious situation of 1914-18. Now, in the fourth year of the war, the authorities are appealing to the Churches and other voluntary bodies to deal with the matter as a great social evil—not, that is, as "an entirely medical matter." This is an advance in the right direction, and it is to be hoped that Mr. Chartres's obscurantist views are too little shared to hinder it.—I am, etc.,

Guildford. G. L. RUSSELL.

SIR,—Mr. E. A. Chartres after fifty years' active practice in many parts of the world among many peoples insists (March 13, p. 331) that venereal disease is entirely a medical matter, and that the sexual is the most important human function we possess. Of course he has some biological backing for his first contention, for, after all, sexually promiscuous lower animals do get sexually transmitted diseases of their own, and sexually promiscuous man does get, in *his* turn, sexually transmitted diseases of *his* own; and no one doubts but that those lower animal infections are entirely a matter for veterinary medicine. So, I take it, let us go in with the beasts!

Possibly now, only a minority of our profession think that we are first of all humans and that the sexual is not the most important human function. I find myself on their side, and, after the opportunities and material for consideration of the problem given me by twenty-three years in medical charge of a treatment centre for venereal diseases, can protest with conviction that prevention of these diseases is primarily a moral, and only secondarily and incidentally a medical, problem.—I am, etc.,

H. M. HANSCHELL,
Albert Dock Hospital, E 16 Director, V.D. Clinic.

Obituary

The death of Dr. S. M. BROWN, hon. consulting surgeon, Southport Infirmary, severs another link with Owens College, where he was prosector and assistant demonstrator of anatomy. Stanley Mewburn Brown qualified M.R.C.S., L.R.C.P. in 1892, M.B. in 1893, and took his M.D.Lond. in 1896. The house appointments he held included those of house-surgeon at the Salford Royal Hospital and at Manchester Royal Infirmary. He went to Southport some 45 years ago, and established a considerable practice there. His membership of the B.M.A. extended over 49 years, and he was chairman of the Southport Division in 1913. He had also been president of the Southport Medical Society and examiner for the St. John Ambulance Association. W. A. M. writes: Appointed assistant medical officer to the Southport Infirmary, Brown passed through the varying ranks, becoming honorary surgeon, chairman of the medical board, and eventually chairman of the infirmary, a position which, with characteristic honesty, he resigned three years ago when he found that his health prevented him from giving it the attention it required. During his chairmanship the infirmary services were considerably extended, and in appreciation of his work a new ward was named after him. I was associated with him for most of his infirmary career, an association which may be taken as characteristic of his influence on his colleagues, for it began with respect, deepened to esteem, and then to affection. Quiet in manner, of sound judgment and knowledge, he influenced by character rather than brilliance; a man diligent in business, upright in conduct, steadfast, and charitable.

We regret to announce the death on Feb. 25 of Dr. JAMES MARR at his home in Greenlaw, Berwickshire. He was born in 1860, the son of the late Mr. William Smith Marr of Tarves, Aberdeenshire, a noted farmer and breeder of Aberdeenshire cattle. James Marr received his early schooling in Aberdeen and went on to study medicine at the University there. He suffered a breakdown in health and travelled to Australia; but on his return he completed his studies, graduating M.B., C.M. in 1892. In the following year he started practice in Greenlaw and devoted himself conscientiously to that work until he retired in 1923. His was a lovable nature, and during his retirement many friends gathered round him to hear of the days when he faced all weathers on horseback and of his early experiences with a motor car. In his latter years his activity was greatly curtailed by crippling osteo-arthritis. In his home there was a large and varied collection of paintings which he had acquired. By his death the poor of the district have lost a good and generous friend. He had been a member of the B.M.A. for 50 years.

Dr. T. B. **Adam**, who died at Harrow on Feb. 27, was one of the pioneers of medicine in Nigeria. Born in Glasgow, Thomas Blane Adam studied medicine at the Royal Infirmary there, qualifying L.R.C.P.&S. in 1900. He took his D.P.H. in 1910. After house appointments at the Royal Infirmary, he entered the Nigerian Medical Service, and was responsible for setting up the first leper colony in that country. Keenly interested in medical missions, he was well known to all the missionaries in Nigeria. His work was arduous, and included the planning of many of the hospitals in use there to-day. When he retired from the service in 1928, after 26 years with it, he became Deputy Director of Medical and Sanitary Services, West African Medical Staff. He did not, however, retire from active participation in the mission cause in Africa; for five years he worked for the Baptist Missionary Society, visiting the Congo and choosing a site for the new hospital at Pimu. Dr. Adam served in the R.A.M.C. in the last war with the rank of major and took part in the Cameroons Expedition.

We regret to announce the death at Liverpool on Feb. 28 at the age of 68 of Mr. **Theodore** R. W. **Armour**, orthopaedic surgeon, Royal Southern Hospital, Liverpool. His health had failed noticeably in the last few months, but he carried on until almost the day of his death.

Theodore Robert William Armour studied medicine at Edinburgh, taking his M.B., Ch.B. there in 1897. Shortly afterwards he was appointed house-surgeon to the late Sir Robert Jones at the Royal Southern Hospital, Liverpool, and during the years he spent under that great teacher he gradually saw orthopaedics develop into a recognized specialty. Among a number of appointments he held were those of surgeon to the Leasowe Hospital for Children, Wirral, the Ministry of Pensions and the Smithdown Road Hospitals, Liverpool. From the outset he entered into orthopaedics with enthusiasm and showed exceptional ability in operative technique; many of his own students have remarked on his manipulative facility. Since his purpose was to obtain the best result for his patient, he grudged neither trouble nor time to that end. His patients, indeed, were quick to perceive this, and their gratitude was a source of happiness to him. For many years he was the senior member of the hospital staff. Here again he always gave his time freely for the discussion of hospital problems and difficulties. A few years before he was due to retire he was made chairman of the appeal committee which had been formed to save the financial position of the hospital. Under his guidance the large sum of money required was successfully raised, and he enjoyed this work, although it involved considerable labour. In the last war he served with the R.A.M.C. with the rank of major. He will be remembered as one who devoted himself to his profession, which he served faithfully and well.

Father **John McAleer**, who died on March 8 at the age of 80, was a medical man, having qualified M.D., M.Ch. at the Royal University of Ireland in 1885. He practised medicine for some years before joining the Society of Jesus at Roehampton over 50 years ago. Since 1900 he had been at Burton Hill, Petworth, Sussex, where he had looked after the sick and aged of the Society.

Supplementing the obituary notice of Mr. I. N. **Blusger** printed on March 20 Mr. R. H. Dale writes: I was a fellow student of Blusger's at St. Bartholomew's, and he held the post of senior house-surgeon while I held the junior appointment. During that time I got to know him really well, and to appreciate to the full his kind and generous character. He was the ideal companion "on the house," and was always ready to help out his inexperienced junior. At that time he was in the hospital rugger fifteen as a fast and fearless centre three-quarter; his fellow South African J. G. Nel played on the wing. I shall always remember Blusger as a true friend and I know he will be greatly missed by all.

The Services

Temp. Surg. Lieut. N. A. Douglas, R.N.V.R., has been appointed M.B.E. (Military Division) for skill and devotion to duty in tending wounded survivors from torpedoed merchantmen.

Surg. Cmdr. C. A. Downward, R.A.N., has been awarded the D.S.C. and Surg. Lieut. D. A. Warden, R.A.N.R., has been mentioned in dispatches for skill, resolution, and coolness while serving in H.M. Australian ships during operations in the Solomon Islands.

The King has conferred the Efficiency Decoration of the Territorial Army on Major (temp. Lieut.-Col.) A. M. Hughes, M.C., Majors W. Bowater, M.C., H. A. Eccles, C. W. F. Greenhill, F. N. N. Roberts, and C. J. Fox, R.A.M.C.

CASUALTIES IN THE MEDICAL SERVICES

Temp. Surg. Lieut. J. de L. Bourgeois, R.C.N.V.R., is included as "missing, presumed killed," in an Admiralty Casualty List published on March 23.

1st Class Assistant Surgeon W. T. J. Monisse, Indian Medical Department, is included as "died" in an India Office Casualty List published on March 19.

Died.—Capt. K. Teevan, R.A.M C.

Prisoners of War.—Lieut.-Col. K. F. Alford, I.M.S, Major B. M. Wheeler, I.M.S.

Missing.—Capt. A. Farquhar, R.A.M.C.

DEATHS IN THE SERVICES

Lieut.-Colonel **Manekshaw Jamshedji Kelawala** died at Ealing on March 20, aged 86. He was a Parsee, who live to greater ages than most Indians. He was educated at the Grant Medical College, Bombay, where he qualified with the L.M.S. in 1879. In the following year he passed the L.R.C.S.Ed. and the L.S.A. and entered the Indian Medical Service. His military service was performed in the Madras Presidency and he saw active service in Burma in 1886-8 with medal and two clasps, and in 1890-2 served with the Tlang-Tlang column with another clasp to his medal. His civil work included the important post of surgical registrar and second surgeon to the J. J. Hospital, Bombay, which is that of the Grant Medical College. He retired in 1909 with the rank of lieut.-col. on the selected list. His widow survives him.

Universities and Colleges

UNIVERSITY OF CAMBRIDGE

The next Final M.B. Examination will begin on Monday, June 14, a day earlier than is prescribed by Ordinance.

The Committee for Medical Radiology and Electrology in its report for the year 1941–2 recalls that the first examination for the Diploma (Part I) was held in July, 1920, and that the regulations for the Diplomas were rescinded on Oct. 31, 1942. The total number of Diplomas granted has been 526 by examination and 34 by thesis only.

UNIVERSITY OF LONDON

The following candidates at the Third M.B., B.S. examination held in Oct., 1942, were approved:

[1,3,4] R. Barer, [1,2,3] Gwendoline R. Briggs, [1,3] S. G. Tuffill, [1,4] D. R. Urquhart, [1,4] B. A. Ward, P. Arnold, Dorothy J. Ball, N. E. Bennett, H. H. Bentall, N. N. Blaxland, A. Bloom, N. R. Carlson, Joyce L. Chamberlain, A. S. Clark, P. J. Collard, G. H. R. Curnock, M. Curwen, I. S. Dalton, Joan M. Daniel, O. Daniel, M. J. G. Davies, V. M. K. Davies, Audrey M. Dealler, Ethel L. Deas, J. L. D'Silva, J. W. L. Doust, Mary E. Egerton, P. D. Fergusson, M. B. Fox, A. H. Galley, B. F. Gans, R. A. Gill, J. F. Goodwin, Mary B. Graham, T. A. W. Green, R. D. M. I-K. Harkness, Mary M. Harrop, H. A. Hasheman, Angela B. G. Hefferman, J. C. Hesketh, W. L. P. Hewerdine, G. Howells, H. Isenberg, D. G. C. Jones, S. L. Kaye, D. H. King, R. King-Brown, A. Kildjian, D'A. Kok, R. U. F. Kynaston, D. G. Lambley, E. Levy, G. H. T. Lloyd, W. C. D. Lovett, Stella M. Luty, Mary K. McCarthy, J. C. Macaulay, P. B. Maling, S. A. Mason, A. H. Michael-Phillips, J. P. Mitchell, R. G. Moore, Joan V. Muller-Rowland, Barbara D. Owens, F. C. R. Picton, D. Reckless, R. G. Rees, H. A. Ripman, Dorothy H. Robertson, J. A. Robertson, Millicent M. Rogerson, Olga B. Ryland, S. C. Sandifer, Irene M. Sarner, B. A. Sellick, J. Sharkey, C. H. Shaw, J. J. Shipman, L. M. Shorvon, J. S. Staffurth, P. B. Stones, P. Stradling, C. G. Stringer, W. V. Taylor, I. F. Thomson, P. A. Thorn, Eileen D. Trafford, P. R. Travers, J. Vahrman, A. A. Vickers, G. G. Wallis, K. W. W. H. Walton, J. F. N. C. Ward McQuaid, Kathleen M. Watson, M. H. West, H. G. Whitworth, K. W. Wilkinson, D. O. Williams, H. G. Williams, H. B. Wright, Mary Young.

The following candidates at the Third M.B., B.S. examination held in Feb., 1943, were approved:

[1,5] C. Campion, [1,4] S. D. Gun-Munro, P. B. Adamson, Margaret E. R. Balfour, G. A. Bedwell, J. Bellamy, Rosemary P. Biggs, J. B. Blacklay, J. J. A. Blakely, D. H. Bodger, J. P. Bound, J. R. Briggs, E. W. C. Buckell, F. H.

Budden, W. F. Cavenagh, D. P. Choyce, S. M. Chris, A. L. M. Christie, Rosemary I. Cook, A. H. C. Couch, Mary H. Cutting, H. Davis, A. J. Duggan, J. G Dumoulin, V. Edmunds, N. R. E. Fendall, J. C. Firth, A. J. Glazebrook, F. T. Graves, W. A. Hamer, G. F. T. W. Henson, H. D. G. Hetherington, Hazel B. Hill, D G Ismay, G. Jarratt, D. B. Jelliffe, A. E. Jones, P. G. Keates, Anna R. Kemp, Monica K. Mack, H B. McLaughlin, B. P. Marmion, P. L. Masters, Jessica Mestel, R. G. W. Moore, T. Parkes, R. T. Parkin, V G. Patel, E. H. Paterson, D. J. H. Payne, S D. Purcell, A. J. H. Rains, J. P. Raw, T. L. Reeves, Edith M. Robson, S. C. Rogers, A. Roth, H. T. N. Sears, J. Shah, H. V-o-M. Shaibany, A. Sherwood, G. R. MacK Sichel, B. Smallhorn, Audrey U. Smith, Edna H Stern, R. J. Stout, F. R. Sutton, M. N. Teubes, D. J. Thomas, H. E. Thomas, L. B. Thomas, D. J. Tibbs, A. B. Tompkins, Edith M. M. Toye, K. O. A. Vickery, R L. Ward, B. G. Wells, W. V. C Wiley, G. F. Wilson, A. W. O Young, H. J. Young.

[1] With honours. [2] Distinguished in pathology. [3] Distinguished in hygiene and forensic medicine. [4] Distinguished in surgery. [5] Distinguished in obstetrics and gynaecology.

UNIVERSITY OF DUBLIN

The following candidates have been approved at the examinations indicated:

M D.—H H. Balch.

M B., B Ch., B A O.—D. M. Bamber, G. H. A. Chamberlain, R H C. Conyngham, A. W. D Cowan, J D. O'Neill Donnellon, A. C. V. Maltby, Mary D Moriarty, O. D. Nightingale, B Novis, T. F. Roche, P. H Seaton, C. Watson, B. A. T. Welsh.

ROYAL COLLEGE OF SURGEONS OF ENGLAND

The following Hunterian Lectures will be delivered at the College, Lincoln's Inn Fields, W.C.: "A Study of the Aetiology of Appendicitis," by Mr. W. H. Bowen, on April 5; "Premaxillary Cysts," by Mr. H. T. Roper-Hall, on April 7; "The Surgery of Non-magnetic Intraocular Foreign Bodies," by Mr. L. H. Savin, on April 9; "Injuries of the Urinary Bladder," by Mr. J. C. Ross, on April 12; "Frost-bite and Kindred Conditions," by Mr. C. R. Greene, on April 14; "Traumatic Arterial Spasm," by Dr. S. M. Cohen, on April 16; "The Vascular Factor in Intracranial Pressure and the Circulation of the Cerebrospinal Fluid," by Prof. J. E. A. O'Connell, on April 19; "The Effect of Ligation on Infection of the Patent Ductus Arteriosus," by Mr. O. S. Tubbs, on April 28; "Cutaneous Innervation," by Dr. G. Weddell, on April 30 and May 3; and "The Treatment of the Injured Workman," by Mr. H. E. Griffiths, on May 5. Prof. H. A. Harris will deliver the Arris and Gale Lectures on "The Anatomy of Posture in Industry" on May 10, "The Clinical Anatomy of the Veins" on May 14, and "The Relationship of the Lymphatic System to the Arterial and Venous Systems" on May 17. Prof. J. Beattie will deliver the Bernhard Baron Research Lectures on "Changes in the Peripheral Vascular System after Haemorrhage" on May 19, and "The Value of Sulphydryl Compounds as Detoxicating Agents" on May 21. All the above lectures will be given at 4 p.m. The Hunterian Oration on "The Forces behind Specialism in Surgery" will be delivered by Mr. Victor Bonney on May 26 at 3.30 p.m. Fellows and Members of the College are invited to attend. Other practitioners and students will be admitted to the lectures on presentation of visiting card.

Medical Notes in Parliament

Nurses Bill

On March 17 Mr. Ernest Brown presented a Nurses Bill, which proposes: (1) The "assistant nurse" (for whom hitherto there has been no accepted definition) shall be given a recognized status and placed on a roll under the control of the General Nursing Council. (2) Employment agencies for the supply of nurses, commonly known as "Nurses' Co-operations," shall be controlled by a system of licensing and inspection. (3) Use of the title of "nurse" shall be restricted to registered nurses and enrolled assistant nurses with certain exceptions.

The first two proposals are in accordance with recommendations of the Athlone Committee, which reported in 1939, and are broadly in line with those of the Nursing Reconstruction Committee of the Royal College of Nursing, which is sitting under Lord Horder's chairmanship. As well as forming a roll of assistant nurses the General Nursing Council will make rules, as they do for State-registered nurses, prescribing the training required, the duration of the training and the institutions at which it may be given, the conduct of examinations, and the conditions of removal of an assistant nurse from the roll. As a transitional step, provision is to be made for the admission to the roll, within two years of the making of the rules, of persons who are at present in bona-fide nursing practice. There will be no examination in these cases, but enrolment will be subject to evidence of good character and satisfactory knowledge and experience of nursing. The Bill provides for a committee of the General Nursing Council, on which assistant nurses will be represented, which will decide questions of removal from or restoration to the roll, and will report to the Council on other questions wholly or mainly affecting assistant nurses.

The Bill prohibits a nursing agency from supplying persons other than registered nurses, enrolled assistant nurses, certified midwives, and other classes to be prescribed by the Minister, and provides for licensing and inspection by the county or county borough council. An agency supplying a nurse, midwife, or other person must state in writing the qualifications of the person supplied, and the agencies must be carried on under the supervision of a doctor or State-registered nurse. Penalties are laid down for breaches of these provisions up to a fine of £100 or three months' imprisonment, or both.

Any person not a State-registered nurse or an enrolled assistant nurse who "takes or uses the name or title of nurse, either alone or in combination with any other words or letters," shall be liable on summary conviction to a fine up to £10, or, in the case of a second or subsequent offence, up to £50. An exception is made in favour of children's nurses.

The Bill also empowers the General Nursing Council to make rules governing the training and qualifications of "sister tutors" employed for the training of student nurses. This follows a recommendation of the Rushcliffe Committee on Nurses' Salaries, in its first report published in February.

The Bill was read a first time.

Mr. Ernest Brown, on March 24, moved the second reading of the Bill. Mr. Hugh Linstead said it went a long way towards closing the nursing profession. He hoped that if Mr. Brown found that prohibition of the use of titles was not sufficient he would come to the House later with additional suggestions. Opposition seemed to be based mainly upon fears of dilution which had not come out into the open. The probability of a universal medical service would increase the demand for nurses and assistant nurses and dilution need not be greatly feared. Sir Francis Fremantle also foresaw an increased demand for the services of nurses. The proposed 96-hour fortnight for nurses in hospitals meant an increase of 20 to 30% in the establishment of many institutions and 20,000 entrants into the profession instead of 12,000 as at present. In order to fill the gap they must make use of the assistant nurses. He believed that the public would realize the difference, and when applying for a nurse would ask for either an enrolled nurse or a registered nurse. He mentioned that Lord Keyes had suggested that sick-berth stewards in the Navy and corresponding men in the Army should be admitted to the full role of State-registered nurses. These men who came from the Services at the age of 45 could do useful work in civil life. He understood that negotiations on this subject had not terminated.

The Bill was read a second time.

Pasteurization of Milk

Asked on March 18 by Mr. Purbrick to prohibit pasteurized milk being fed to babies without notification, Mr. Brown said he would not do so. He was advised that the keeping quality of milk was much improved by pasteurization and that there was no scientific evidence for the statement that pathogenic organisms grew better in pasteurized milk than in clean raw milk.

In reply on the same date to Mr. Ness Edwards Mr. Brown said he had seen the latest report of the Caerphilly medical officer of health, which stated that the supply of heat-treated, not pasteurized, Carmarthen milk to schools would lead to a grave increase in bovine tuberculosis in the next few years. He did not know on what evidence it was said that the heat treatment of the milk in question had been insufficient to destroy tubercle bacilli. He would make further inquiry. He was consulting with the Minister of Food on the general question of providing the practicable maximum supply of adequately heat-treated milk. In the meantime the milk referred to could be made safe by boiling it.

Tuberculosis Mortality

On March 23 Mr. Douglas asked the number of deaths from pulmonary and non-pulmonary tuberculosis, respectively, which occurred in 1938 in classified areas of England and Wales. Mr. Ernest Brown furnished the following table:

	Respiratory	Other Forms
London Administrative County	2,590	347
Croydon County Borough	117	20
East Ham County Borough	81	8
West Ham County Borough	172	19
The rest of Greater London	1,777	318
Outside Greater London:		
County Boroughs	8,474	1,492
Other Urban Areas	5,968	1,375
Rural Districts	2,751	667

Notes in Brief

The proportion of men invalided from the Army suffering from neurosis was in 1942 about 17% of the number invalided out of the Army in that year on account of all diseases.

Medical News

The Therapeutic Requirements Committee of the Medical Research Council draws attention to the need for strict economy in the use of desoxycorticosterone acetate. This is an essential drug for the treatment of Addison's disease, and the supplies available are only sufficient for this purpose. There is no evidence that desoxycorticosterone acetate is essential in any other condition. Practitioners are therefore again urged not to prescribe desoxycorticosterone acetate for any patients except those suffering from Addison's disease. If it is desired to use adrenal cortical therapy in conditions other than Addison's disease, practitioners should prescribe the natural extract of adrenal cortex, of which adequate supplies are available from glands collected in this country.

The annual meeting of the Medical Superintendents' Society will be held at B.M.A. House, Tavistock Square, W.C., on Saturday, April 17, at 2 p.m.

The Society of Thoracic Surgeons of Great Britain and Ireland will hold a meeting at the Royal Society of Medicine, 1, Wimpole Street, W., on Wednesday and Thursday, April 14 and 15. The subjects for Wednesday at 2 p.m. are the first-aid treatment of chest wounds and injuries, and the early and late treatment of retained foreign bodies. On Thursday at 9.30 a.m. the society will discuss the role of the general surgeon in the treatment of chest wounds in forward areas, and at 2 p.m. the treatment of pleural empyema. Officers of the British, Dominions, and Allied medical services and general surgeons of the E.M.S. will be welcome, after obtaining permission from their own higher authorities.

The Ministry of Supply (Rubber Control) has a quantity of rubber gloves of a good household quality which it is prepared to sell in reasonable numbers and for essential purposes for use in hospitals, clinics, and mortuaries. They are suitable for many uses for which surgical gloves are normally required in these institutions. Application should be made to the Secretary, Ministry of Supply (Rubber Control), Empire House, St. Martin's-le-Grand, London, E.C.1, who will give the names of firms from which the gloves may be obtained.

EPIDEMIOLOGICAL NOTES

Discussion of Table

In *England and Wales* during the week there was a rise of 599 in the number of notifications of measles and a fall of 135 in the number of cases of pneumonia. Small decreases were recorded for scarlet fever 21, whooping-cough 12, and diphtheria 33, while there was an increase of 10 in cases of dysentery. Scarlet fever and diphtheria showed only small fluctuations locally, and the largest variation in the incidence of whooping-cough was a fall of 59 in London. There were big differences within the counties in the incidence of measles. After seven weeks of rising notifications the returns for London showed a fall of 57. Other large decreases were those of Middlesex 263, Gloucestershire 129, Essex 129, Wiltshire 73, Cheshire 66, and Kent 62. The largest rises were those of Glamorganshire 188, Devonshire 171, Lancashire 169, Somersetshire 150, Yorks West Riding 127, and Surrey 125. No new outbreak of dysentery was reported during the week, and the rise was due to sporadic cases. The 78 cases were reported from 25 counties.

In *Scotland* the chief features of the returns were increases in the incidence of measles 52, scarlet fever 41, and whooping-cough 38. The number of cases of measles has increased steadily during the past four weeks, and the total is now 60% higher than at the beginning of this period. During the week reviewed there was a small rise in all areas except the western, where a slight decline from 352 to 344 cases was recorded. The largest increases were those of Zetland County 26, and the city of Edinburgh 17. A small rise in the notifications of scarlet fever was fairly general throughout the country. The increase in the cases of whooping-cough was due to the experience of Glasgow, where the number of cases rose from 109 to 155.

In *Eire* the large rise in cases of whooping-cough was due to the outbreak in Waterford C.B. 36 cases, and to the inclusion of 30 cases from a Dublin institution which have occurred since the beginning of the year. A further 36 cases of diphtheria were reported from the outbreak in Dublin.

The Week Ending March 20

The notifications of infectious diseases in England and Wales during the week included: scarlet fever 2,160, whooping-cough 2,007, diphtheria 798, measles 19,409, acute pneumonia 1,304, cerebrospinal fever 95, dysentery 66, paratyphoid 8, typhoid 13. In the great towns there were 52 deaths attributed to influenza.

No. 10

INFECTIOUS DISEASES AND VITAL STATISTICS

We print below a summary of Infectious Diseases and Vital Statistics in the British Isles during the week ended March 13.

Figures of Principal Notifiable Diseases for the week and those for the corresponding week last year, for: (a) England and Wales (London included). (b) London (administrative county). (c) Scotland. (d) Eire. (e) Northern Ireland.

Figures of Births and Deaths, and of Deaths recorded under each infectious disease, are for: (a) The 126 great towns in England and Wales (including London). (b) London (administrative county). (c) The 16 principal towns in Scotland. (d) The 13 principal towns in Eire. (e) The 10 principal towns in Northern Ireland.

A dash — denotes no cases; a blank space denotes disease not notifiable or no return available.

* Includes primary form for England and Wales, London (administrative county), and Northern Ireland.

† Includes paratyphoid A and B for Northern Ireland.

‡ Owing to evacuation schemes and other movements of population, birth and death rates for Northern Ireland are no longer available.

Letters, Notes, and Answers

All communications in regard to editorial business should be addressed to THE EDITOR, BRITISH MEDICAL JOURNAL, B.M.A. HOUSE, TAVISTOCK SQUARE, LONDON, W.C.1

ORIGINAL ARTICLES AND LETTERS forwarded for publication are understood to be offered to the *British Medical Journal* alone unless the contrary be stated.

Authors desiring REPRINTS should communicate with the Secretary of the Journal Board, B.M.A. House, Tavistock Square, W.C.1, on receipt of proofs. Authors over-seas should indicate on MSS. if reprints are required, as proofs are not sent abroad.

ADVERTISEMENTS should be addressed to the Advertisement Manager (hours 9 a.m. to 5 p.m.). Orders for copies of the *Journal* and subscriptions should be sent to the Secretary.

TELEPHONE No.—B.M.A. and *B.M.J.*: EUSTON 2111.

TELEGRAPHIC ADDRESSES.—EDITOR, *Aitiology Westcent, London;* SECRETARY, *Medisecra Westcent, London.*

B.M.A. SCOTTISH OFFICE: 7, Drumsheugh Gardens, Edinburgh.

ANY QUESTIONS?

Pain in Hernial Scar

Q.—*I should be grateful for advice concerning treatment of severe pain in the region of bilateral inguinal hernia repair scars. A male patient aged 50 had in 1941 a bilateral Bassini operation. Fourteen months later he had to have a repair for a recurrence of the right hernia (suturing conjoined tendon to Poupart's ligament behind the cord and suturing a strip of external oblique aponeurosis to the conjoined tendon). He has been advised a further operation, but is neither willing nor fit enough to undergo this. Both cords are very tender. A suspensory bandage helps a little, but he has to have large doses of an analgesic to get any real ease.*

A.—The most frequent cause of pain in the hernial region such as the patient complains of is the inclusion of the ilio-inguinal nerve in a suture. Only an operation for dividing the nerve is likely to bring relief. An alternative suggestion to explain the pain would be the too tight closure of the internal abdominal ring round the cord. In any case relief is only to be secured by operation by someone who knows some anatomy.

Sulphonamides for Gonorrhoea

Q.—*Is there a consensus of opinion regarding the treatment of gonorrhoea by sulphonamides? When should treatment begin? Which of the sulphonamides gives the best results? What is the duration of treatment? What is the standard of cure?*

A.—The answer to the first question is, Yes. A smear should be taken and treatment started at once. Sulphathiazole (or sulphadiazine) 6 g. a day in divided doses should be given for two to four days; plenty of fluids should be taken at the same time. The standard of cure is absence of discharge and clear urine containing no heavy threads. Examine for above daily for a few days after cessation of treatment, then once weekly for three weeks. The final test of cure is made at the end of three months; this includes bacteriological examination of the urine and of prostatic and vesicular secretions, urethroscopy, and passage of curved sounds. A Wassermann reaction is taken to exclude concomitant syphilitic infection. A gonococcal complement-fixation test is useful, especially if there have been any complications.

Treatment of Diphtheria Carriers

Q.—*A boy of eleven was immunized at school one or two years ago. In January of this year he got a sore throat and pyrexia. Throat swab showed diphtheria bacillus and haemolytic streptococcus The latter disappeared under the influence of sulphapyridine, but the throat continues to be positive for diphtheria bacillus; the nose is negative. Clinically there was no evidence of diphtheria, but I kept him in bed for four or five weeks, fearing the systemic manifestations of diphtheria. For a month both nose and throat were sprayed with equal parts of sulphapyridine and sulphathiazole powder, but I have not been able to get more than two negative throat swabs in succession. An old country doctor says that the best treatment for these carriers is carbolic. I should be grateful for a summary, in order of merit, of the methods of treating diphtheria carriers.*

A.—It is very probable that this was a case of haemolytic streptococcal throat infection in a diphtheria carrier—i.e., diphtheria bacilli not only were present in the throat during and after the attack but had been there before without at any time causing ill effects, the boy being immune. This could have been verified at the time of the attack by doing a Schick test. A persistent throat carrier usually has hypertrophied tonsils, in the crypts of which diphtheria bacilli are inaccessible to local applications. It is chiefly for this reason that treatment with antiseptics is disappointing, and carbolic acid is no more likely to be successful than others. The proper treatment for such cases is tonsillectomy: the condition of the tonsils is usually an indication for this, apart altogether from the carrier state which accompanies it. Nasal carriers fortunately respond better to antiseptic treatment, the organism being more superficially situated, and the flow of mucus so comparatively slow that applications are not rapidly washed away as from the throat by swallowing. Good results have been reported from the use of sulphathiazole snuff (1 part of sulphathiazole to 2 parts of magnesium carbonate taken as snuff 6 times daily).

Oestrogens and Cancer

Q.—*Is it safe to continue giving stilboestrol to a patient over several years? Is there any likelihood of cancer developing as a result of its use?*

A.—Prolonged administration of oestrogens, of which stilboestrol is one, may undoubtedly be injurious. Stilboestrol in normal dosage causes proliferation of the tissues of the female secondary sex organs —tubes, uterus, vagina, and vulva. If given in large doses, however, it produces pathological hyperplasia of the endometrium and consequent profuse uterine haemorrhage. This occurs even in post-menopausal women. In still more prolonged oestrogen therapy an inhibitory effect on the pituitary and ovary becomes manifest, and the ultimate result is atrophy of the uterus and allied structures. Thus if a patient is being treated with stilboestrol for uterine hypoplasia the duration of treatment should be strictly limited; otherwise the final result is exactly opposite to the one desired. In the male, pituitary depression, injury to testicular function, and atrophy of the secondary sex organs likewise result. Other ill effects of prolonged treatment which have been postulated but not proved clinically are liver damage and, under certain conditions, the development of uterine fibroids and pelvic endometriosis.

Available evidence does not permit a definite conclusion as to whether stilboestrol can initiate cancer. All oestrogens are powerful epithelial stimulants, affecting chiefly the tissues of the breast, uterus, vagina, and vulva. The withholding of oestrogens or ovarian stimulus inhibits the growth of mammary carcinoma in mice, whereas the administration of oestrogen encourages it. A considerable body of experimental evidence of this type in relation to carcinoma, not only of the breast but of the uterus and other organs, is supported by the less convincing clinical observations that cancer, particularly of the secondary sex organs, usually develops rapidly when the organism is flooded with oestrogen (as in pregnancy), whereas removal of the ovaries tends to inhibit the growth of uterine and mammary cancer. Also, carcinoma is not infrequently seen in uteri already the seat of innocent endometrial hyperplasia, and this latter is undoubtedly the result of an oestrogen stimulus. Moreover, many cases of genital carcinoma arising in women under treatment with stilboestrol have been recorded, but the association has not yet been proved to be other than coincidental. In view of such considerations, and until the contrary is proved, it must be admitted that there is a possibility that long-continued administration of stilboestrol will determine the onset of carcinoma, at least in the female secondary sex organs, in *some* circumstances. According to animal experiments these circumstances are an inherited predisposition, or local injury, or chronic infection. Stilboestrol, therefore, should be given with great caution to any patient known to have a "pre-cancerous" lesion in the breast or genital organs—such as chronic cervicitis or leukoplakia vulvae.

LETTERS, NOTES, ETC.

Age and Perforation of Peptic Ulcer

Mr. W. M. BEATTIE, F.R.C.S. (Liverpool) writes: I was interested in Dr. David Kyle's case of a perforated gastric ulcer at the age of 19 (March 20, p. 370). I have not met perforation of a gastric ulcer at such an early age, but I recently operated upon two patients, a boy aged 16 and a girl aged 18, for perforated acute duodenal ulcer. Incidentally, about the same time I sutured a perforation of a duodenal ulcer in a man aged 74. It would seem that we are safe from this abdominal catastrophe only during the first decade of life.

Waste Paper

Paper has to be found for the wrapping of surgical dressings, waddings, medicines, diet and temperature charts, and for a multitude of other medical purposes. For example, the wallboard of some hospital huts is produced from pulped waste paper and cardboard. Medical chests for use in the Tropics are made from laminated plastic material consisting of layers of paper impregnated with a synthetic resin. Doctors are therefore urged to do what they can, in company with everyone else, to turn out their waste paper. May we suggest that some of the magazines in the waiting-rooms are now sufficiently out of date?

Correction

EXPERIENCES WITH TYPING OF TYPHOID BACILLI BY MEANS OF Vi BACTERIOPHAGE*

BY

A. FELIX, D.Sc., F.R.S.

(From the Emergency Public Health Laboratory Service)

The latest development in the study of the epidemiology of typhoid fever is the discovery made by Craigie and Yen (1938a, 1938b) of type-specific typhoid Vi bacteriophages. Until then the typhoid bacillus had been regarded as a single species without varietal subdivision. By the use of the new technique devised by Craigie and Yen it is now possible to divide typhoid bacilli into a number of well-defined types. The story of this discovery may be briefly summarized here.

Hadley (1925-6), Burnet (1927, 1929), and Levine and Frisch (1934) were the first to show that the action of bacteriophages on the various Salmonella species is closely related to the presence of certain heat-stable "O" antigens in the bacterial cell. Later studies on dysentery bacilli (Burnet and McKie, 1930), the cholera vibrio (Bruce White, 1936), and other pathogenic organisms also showed a close relationship between antigenic structure and phage susceptibility. As soon as the special importance of the so-called "Vi" antigen of the typhoid bacillus was recognized (Felix and Pitt, 1934) a number of authors, working independently of each other in different countries, established the existence of bacteriophages that were specific for the Vi form of the typhoid bacillus (Sertic and Boulgakov, 1936; Scholtens, 1936; Craigie and Brandon, 1936). These phages attacked typhoid strains irrespective of their origin, provided the cultures contained an adequate quantity of the Vi antigen. By propagating a particular anti-Vi phage on typhoid strains isolated from different sources Craigie and Yen (1938a) obtained bacteriophages which had developed a high degree of specificity for the particular strain on which they were grown. When such adapted phage preparations were tested against a great number of typhoid strains from different localities it was found that the strains could be divided according to their response to the different phage preparations and that strains that were related epidemiologically belonged to the same phage type. On this basis Craigie and Yen identified a number of distinct types of *Bact. typhosum*. A small proportion of Vi cultures cannot be typed in this way, for reasons that are not yet understood. Such cultures are referred to as "imperfect" Vi forms.

The phage type of a strain is for all practical purposes a permanent character, and typing of the typhoid bacillus by this means gives results as reliable as those obtained in streptococcal or pneumococcal infections by the use of serological tests. It may be stated in passing that the Vi antigen of typhoid strains belonging to different phage types cannot be differentiated by any of the customary serological methods (Felix and Pitt, unpublished results). The few reports on the application of the new method that have been published so far from Canada (Brandon, 1940), the United States of America (Lazarus, 1941), and China (Yen, 1939) have all corroborated the observations of Craigie and Yen. In this country Boyd (1939) drew attention to the potential value of this discovery.

The method of phage typing has been employed in the Emergency Public Health Laboratory Service since 1940. Cultures of *Bact. typhosum* isolated in the constituent laboratories of the E.P.H.L. Service and in some other public health or clinical laboratories in England, Wales, and Scotland have been submitted to a reference laboratory for typing by the bacteriophage technique. The object of this paper is to give an account of the results so far obtained from this material.

Technique

The technique of the test followed as closely as possible that described in the original paper by Craigie and Yen (1938a), and need not be discussed here in detail. Early in 1940 Dr. J. Craigie of the Connaught Laboratories, Toronto, very kindly supplied the complete collection of his standard phage preparations and standard type cultures, together with a copy of his "Notes on the Typing of *B. typhosus* with Vi Phage," dated March, 1940, and embodying further technical details. The number of standard phage preparations recommended at that time by Craigie for use in routine typing was 18, representing the following types and subtypes: A, B1, B2, B3, B4, C, D1, D2, D3, E1, E2, F1, F2, G, H, J, L, and M. All the cultures examined in the course of the present investigation have been tested against these 18 type and subtype phages. For reasons of economy only the phages corresponding to the more common types were employed singly; the others were used in appropriately pooled mixtures.

Cultures of *Bact. typhosum* isolated in the course of the routine examination of typhoid patients or carriers were submitted for typing as soon as the organism had been identified by the customary cultural and serological methods. Some of the laboratories sent the subcultures on Dorset egg medium, others on plain agar slants or in plain agar stabs. The cultures were sent by post, and usually reached our laboratory within 4 or 5 days from the date of isolation. In many instances much older cultures were received, and these, too, were usually found to be suitable for typing. The only precaution taken was that the bacteriologists in charge of the various laboratories were asked to prepare the subcultures not from a single colony but, whenever possible, from about half a dozen selected "smooth" colonies which were seeded together on a slant of Dorset egg medium or plain agar. The pooling of a number of colonies is a useful safeguard against the chance selection of a single colony, which, though smooth-looking (Arkwright, 1930), may be composed of bacteria that are deficient in the Vi antigen or do not contain any Vi antigen ("O" forms).

The great majority of typhoid strains handled in this way gave a clear-cut result in the phage typing when the subculture required for the test was prepared directly from the original culture tube received. The result of the typing could thus be reported within 24 or 36 hours. If the phage tests on the original culture failed to give a clear-cut result, or if the strain was found to be an untypable "imperfect" Vi form, the tests were repeated. The culture was plated out on plain agar, and a number of single-colony cultures or a pooled culture that had been derived from at least half a dozen carefully selected "smooth" colonies were retested against the type phages. If the strain still remained untypable another culture was, when possible, obtained from the patient or carrier, and some of these repeat cultures, especially those from chronic carriers of long standing, were found to be typable.

---

* A report to the Medical Research Council.

Typhoid Vi-phage Types Prevalent in England, Wales, and Scotland during 1940–2

The total number of cultures submitted to the phage typing test was 643. The number of typhoid patients and carriers from whom the strains had been derived was 440. In 87 cases the cultures were isolated from the blood; in a few instances from the urine or from post-mortem material; and the majority were obtained from faecal specimens. Thirty-five cultures had been isolated from samples of polluted water and sewage effluents. The remaining 168 cultures were obtained in the course of repeated examinations of the excreta of some of the patients and carriers. These repeat tests were carried out with a view to collecting further evidence regarding stability of the types, or as part of certain special investigations which are to be reported elsewhere. Table I shows the number of types and subtypes of the typhoid bacillus that have been met with in this country, and indicates their prevalence during the past three years.

Part I of the table shows that 9 of the 18 types and subtypes of Craigie's original schema were found among the strains isolated in the United Kingdom. Type J has been included in the list for the sake of completeness, although that type is not prevalent in this country. One of the two Type J cases recorded in the table was a faecal carrier who had contracted typhoid fever in Egypt during 1940 and returned here in 1941. Six weeks later he passed on the infection to his brother-in-law, who died from his attack of typhoid fever. The remaining 8 types and subtypes, however, must all be considered as indigenous to this country. These 8 types were also represented among the late W. M. Scott's collection of English strains that had been examined by Craigie and Yen (1938b). Scott's collection comprised 74 cultures isolated from most of the major outbreaks of typhoid fever that occurred in England and Wales during the period 1932 to 1938.

It is too early to draw any conclusion on the relative frequency of the various types, because the figures shown in Table I represent only a fraction of the total number of typhoid cases notified during the three years under review. Most of the strains recorded in Table I were isolated from patients belonging to small groups of cases or from sporadic cases scattered throughout the country; but a few somewhat larger outbreaks also occurred, and some of these resulted in 10 or 20 cultures from the same outbreak being typed and included in the list. Finally, some of the laboratories that were supplying the cultures were able to examine most of the typhoid cases that occurred in their area, whereas other laboratories elsewhere were not in a similar position. The figures shown in Table I therefore afford no more than a rough indication of the distribution of foci due to typhoid strains of the various Vi-phage types.

It is seen from Part I of the table that the strains isolated from 126 patients or carriers could not be typed with the original type phages of Craigie. Only 8 of these strains were "O" forms, which did not contain any Vi antigen. The remaining 118 strains, or 26.8% of the total number examined, were "imperfect" Vi forms—that is to say, the strains were resistant to the action of the 18 specific type phages in spite of the fact that the cultures contained the Vi antigen and were readily lysed by the concentrated non-specific Vi phages that are employed as control reagents in the test.

Part II of Table I shows that 49 strains, or 41.5% of the "imperfect" Vi forms, were later successfully typed by means of four new Vi-type phages. The new phage preparations were obtained by a process of adaptation similar to that employed by Craigie and Yen (1938a). The new types were provisionally labelled D4, D5, L2, and No. 91. Type D5 has been encountered on only one occasion, and may possibly have been introduced from abroad. The patient was an Indian soldier who suffered from an attack of typhoid fever a few months after he had arrived in this country. The other new Vi types are firmly established here. Type L2 was found in Scotland as well as in England. Type 91 has already been identified in eight different counties, widely separated from each other, and a strain belonging to this type has been isolated from a chronic carrier of long standing—a woman aged 70 A strain of Type D4 has also been found in a chronic carrier —a man aged 66 who has never lived abroad.

From a practical point of view the result of the typing of this series of cases is very satisfactory. If the 8 strains that were available only in the "O" form are disregarded, it is seen that the number of "imperfect" Vi forms which could not be typed was 69, or 15.9% of the total number of Vi forms examined. More than half were strains derived from three outbreaks, and these might have been typed successfully had special efforts been made at the time the outbreaks occurred. Thus the number of separate foci of infection in which the phage type remained unidentified was very small indeed.

A few typhoid strains from patients and carriers who contracted the infection abroad were also examined in the course of this investigation, and it may be of interest to record these cases here. The carrier of Type J bacilli of Egyptian origin has been already mentioned. The other cases belonged to the following types: Type A—from Chile and Russia; Type D1 —from Eire and the Faroe Islands; Type E1—from Belgium and Malta.

It is obvious that workers in different countries who are employing the bacteriophage typing method should maintain close contact and exchange cultures and phage preparations before new types or subtypes are recognized and added to the original schema of Craigie and Yen. At the present time it is rather difficult to adhere to this rule, and some confusion concerning nomenclature is likely to arise. So far only Type D4 cultures and the corresponding phage preparations have been sent to Dr. Craigie, who reported that in his opinion D4 was a new Vi-phage type. The designations chosen for the four new types must necessarily be provisional, pending revision after the war, when co-operation between workers in different countries will again be possible. Craigie (1942) suggested a revised and simplified typing schema, but his investigations regarding the required phage preparations have apparently not yet been completed.

Epidemiological Significance of Typhoid Vi-phage Types

The observations of Craigie and Yen on the epidemiological significance of Vi-phage types of typhoid bacilli have been amply corroborated in the course of the present investigation. Patients from any given outbreak of typhoid fever yielded cultures belonging to the same Vi-phage type. Strains from chronic carriers, when repeatedly isolated over long periods, did not show any change from one type to another. Carrier strains do, however, often show antigenic degradation leading to the appearance of "imperfect" Vi forms and of "O" forms, neither of which can be typed. Of the 8 strains recorded in Table I as "O" forms, 6 had been isolated from chronic carriers of many years' standing and only 2 from typhoid patients.

It is not proposed to state here in detail the number of outbreaks investigated or the number of patients examined during each outbreak. The cases summarized in Table I include a considerable number of small outbreaks, each affecting from 3 to 6 members of a family or household; cases of direct contact infection of nurses attending typhoid patients; outbreaks in mental hospitals, hostels, and camps, affecting groups of about 20 patients, from whom typhoid cultures have been examined. It is noteworthy that the results of the typing were in accord with the epidemiological observations; that is to say, all cases infected from the same source were found to have been caused by the same Vi-phage type of typhoid bacillus. Similarly each of the chronic carriers tested, who according to epidemiological evidence appeared to be responsible for an outbreak, was harbouring typhoid bacilli of the same Vi type as that isolated from the patients.

There were in this series two apparent exceptions to this rule, one of which, however, proved to confirm it. The first concerned an outbreak in a mental hospital, which was investigated by Dr. R. M. Fry of the E.P.H. Laboratory, Carmarthen. In this case most of the convalescent patients were excreting Type E1 bacilli, but a few yielded Type C. Dr. Fry succeeded in detecting among the mental patients chronic carriers of the two different strains, thus proving the presence of the separate sources of infection. The other instance of apparent disharmony between epidemiological data and laboratory findings concerned an outbreak in a large industrial city. All the patients had evidently contracted the infection from the same source, a butcher's shop, yet the cultures belonged to two bacteriophage types. The patients had been treated in a number of hospitals, and the cultures were received for typing from three different laboratories several weeks after the outbreak had occurred. Two of the laboratories sent only cultures of Type E1, and the third laboratory only cultures of Type F2. It was unfortunately not possible to obtain repeat specimens, as all the patients had been discharged from hospital by the time the cultures were typed. In view of the existing evidence as to stability of Vi types it seems justifiable to assume that this quite exceptional finding was due to an accident during the handling of the cultures.

The Practical Value of the Typing Method

Some of the cases recorded in Table I have been the object of special epidemiological investigations conducted by the Ministry of Health, in co-operation with the E.P.H.L. Service. The story of one of these investigations is told by Dr. W. H. Bradley at page 438. This fascinating story ended with the unmasking of the chronic carrier who was responsible for a score of typhoid cases of Type D4 that occurred over a wide area during a period of nearly two years. Bradley's report and my own related experiences in the course of a number of similar inquiries indicate clearly that the value of the typhoid typing method cannot be emphasized too strongly. Without this new laboratory aid there can be little hope of determining the source of infection of many of the sporadic cases, and small groups of cases, that occur throughout the country.

To illustrate this point Table II has been compiled, showing the sequence of typhoid cases that were examined in one single county during a period of 16 months. The list has been arranged in chronological order, though in abridged form. Most of the cultures were isolated by Dr. J. C. Cruickshank of the E.P.H. Laboratory, Exeter.

The table shows that cases belonging to at least six typhoid Vi types occurred in Devonshire during the period under review. The cases therefore originated from at least six different sources of infection. The topographical distribution makes it very likely that the number of active foci was considerably greater. It is clear that the medical officers of health who are called on to investigate sporadic cases in these circumstances are at present faced with an almost impossible task. The epidemiological investigations cannot lead in the right direction unless the infections that arise concurrently from a number of different sources are first separated one from another. The bacteriophage test is at present the only laboratory method that makes this separation possible.

* Typhoid cases or carriers among mental patients are not included in the list.

Typhoid fever is now an uncommon disease in this country, but it would be wrong to assume that it is already in process of extinction, as some recent writings suggest. Endemic foci of the infection, maintained by chronic carriers, still exist in many parts of the country, and the case of Devonshire may serve as an example. How numerous these foci are can only be guessed at the present time. The diagnosis of the enteric fevers has not been satisfactory in rural districts, and it is still not uncommon for typhoid cases to be missed, the diagnosis having been made only at the post-mortem examination or not at all. Since the outbreak of the present war some of these areas have been provided with facilities for diagnosing enteric fevers by means of adequate laboratory methods. If these facilities could be made available throughout country districts generally, the number of enteric cases that remain undiagnosed would soon decrease very considerably.

Although bacteriological differentiation into typhoid and paratyphoid fever has been possible in some areas for many years, the enteric fevers have, for purposes of notification, been regarded as a single entity until recently. In July, 1941, it became practicable to separate the two diseases in the weekly returns of the General Register Office. The following table has been reconstructed from this source.

Notified Cases of Enteric Fevers in England and Wales

	1938	1939	1940	1941		1942
				Jan.–June	July–Dec.	
Typhoid fever ..					677	464
Paratyphoid fever ..					2,941	404
Total typhoid and paratyphoid fevers	1,322	1,479	2,833	1,145	3,618	868

In 1940 and 1941 numerous outbreaks of paratyphoid B fever occurred, and the table shows that during the last six months of 1941 the number of notified cases of paratyphoid was four times that of typhoid. In 1942, on the other hand, there were no large outbreaks of either of the two diseases, and the total number of cases was the lowest ever recorded in England and Wales. The interesting point is that during this rather exceptional "non-epidemic" year the numbers of notified cases of typhoid and paratyphoid were about equal, and this year probably indicates the relative numbers of endemic foci of the two diseases more accurately than does a year in which larger outbreaks occurred. It would be premature, however, to draw any conclusion from the figures so far available.

The control of typhoid fever depends ultimately on the control of the chronic carrier. The detection of a chronic carrier who is responsible for the infection of sporadic cases or of small groups of cases is usually a very difficult task. The introduction of refined culture media, particularly the bismuth sulphite medium of Wilson and Blair (1931), and of the Vi agglutination test, has made the problem less formidable than it was in earlier days. The new typing method devised by Craigie and Yen (1938a) has provided another weapon of great efficacy. It now seems possible to organize the fight against the chronic typhoid carrier in a manner that promises to lead far towards the ultimate goal, the eradication of the disease.

Summary

During 1940–2 440 strains of typhoid bacilli isolated in England, Wales, and Scotland were examined by the Vi bacteriophage method of Craigie and Yen. Of 432 strains that were Vi forms 363 (84.1%) were successfully typed, while 69 (15.9%) were untypable, or "imperfect" Vi forms. The remaining 8 strains, including 6 from chronic carriers, could not be typed because the cultures were "O" forms.

Most of the strains belonged to 8 of Craigie's original phage types. In addition 4 new Vi-phage types were identified.

The bacteriophage test is a reliable guide to the epidemiological investigation of outbreaks or sporadic cases of typhoid fever. Its application greatly facilitates the detection of chronic carriers, especially those responsible for sporadic cases in endemic areas.

Unquestionably the new method will soon be recognized as an indispensable laboratory aid to the control of typhoid fever.

This investigation was made possible by the co-operation of many pathologists, medical officers of health, and superintendents of fever hospitals, and by the constant aid of Dr. J. R. Hutchinson and Dr. W. H. Bradley of the Ministry of Health. I wish to thank all of them for their help. My thanks are also due to Miss B. R. Callow for help in maintaining the cultures.

AN ENDEMIOLOGICAL STUDY OF BACT. TYPHOSUM TYPE D4

BY

W. H. BRADLEY, D.M.

A Medical Officer of the Ministry of Health

During the period 1871-5 enteric fever killed annually 371 persons per million living in England and Wales. The "complex armour of modern sanitation" now protects us from the major epidemics of 70 years ago; but, even so, the mortality rate during the past 10 years has remained constant at about 6 per million living, and this residuum appears to be due to causes resistant to existing preventive measures. The final extinction of enteric fever may be possible when these resistant causes are better understood; for this reason studies of endemicity as distinct from epidemicity are of special interest, and the detailed investigation of a series of apparently solitary cases, although all too disappointing, may on occasion prove unexpectedly fertile.

The importance of sporadic cases and the frequency with which they occur are not always recognized. For instance, approximately one-half of the total number of towns in which enteric fever appeared in the first six months of 1940 had only one case apiece. We may, with some justification, attempt to measure the efficacy of the "complex armour" by counting the number of sporadic cases which fail to initiate outbreaks, but at the same time it is well to remember that each such case—and they are for the most part of unknown origin—is a warning that chinks in the armour exist. Nowadays an explosive outbreak, particularly of paratyphoid fever, can generally be attributed to the undetected sporadic case which, by virtue of opportunities presented by the subject's employment, infects a widely consumed aliment (Savage, 1942). Presumably the chronic carrier is always somewhere in the background, but his relation to a series of cases may be remote, and he all too frequently evades detection.

The late W. M. Scott (1941) had written in this vein a short while before his death in April, 1941. Scott realized the epidemiological significance of the discovery by Craigie and Yen (1938) that typhoid bacilli could be typed according to their sensitiveness to certain Vi bacteriophages.

Phage Typing of Bact. typhosum

During 1940 the Emergency Public Health Laboratory Service began to concentrate investigations of typhoid cultures in a special laboratory, where Felix (see p. 435 of this issue) was able to build up a representative collection of the various phage types of *Bact. typhosum*. Up to the present 12 types have been recognized as giving rise to disease in this country, including four types or subtypes not previously described. The original strain of one of these, D4, was recovered from the blood of Case 1 in the series here described. This case was solitary, sporadic, and entirely unexplained at the time: it is distinguished as Case 1 only because it gave the first strain of Type D4 *Bact. typhosum*. We know nothing concerning the ancestry of D4 beyond the fact that it was apparently not represented in Scott's collection of 70 strains found in the country during the previous decade nor by Felix among 80 strains freshly isolated during 1940. Presumably uncommon, it promised to be a suitable subject for a sustained attempt to exploit phage typing in a field investigation; and subsequently, wherever and whenever Type D4 was recovered from a patient or a carrier exhaustive epidemiological investigations were made personally. Prof. G. S. Wilson collaborated throughout the inquiries, and a note on the preliminary observations appeared in the *Bulletin of the Emergency Public Health Laboratory Service* (March, 1941).

Chronology of Cases of Type D4 Typhoid identified in England and Wales, 1941-2

Nineteen D4 excreters have been detected, and all are listed in the accompanying table, which also includes five persons believed to have been infected with this organism but from whom no cultures were submitted to typing. It is significant that this list contains every case of typhoid fever notified in Buckinghamshire during 1941 and most of those occurring in the county during 1942, although in this year another type also appeared.

Cases in 1941

Case 1.—An itinerant merchant, living in Hertfordshire, who disliked milk was in bed intermittently from Jan. 4 to Jan. 10, 1941, when his doctor diagnosed pneumonia. By Jan. 17 he was able to take solid food. On Jan. 20 his temperature began to rise again, and reached 104.0° by Jan. 27, when he was admitted to hospital in coma. A petechial rash appeared; septicaemia was diagnosed, and blood was taken for culture on Jan. 28 and Jan. 31. Death occurred on Feb. 4. Enteric fever did not enter the minds of the medical officers performing the necropsy, but it was subsequently reported that typhoid bacilli were recovered from his blood. When this man first took to his bed he was put on a diet of raw milk purchased from retailer "A"; it is conjectured, for reasons which will appear subsequently, that this milk contained Type D4 *Bact. typhosum* on or about Jan. 8.

Cases 2 to 9.—Between Feb. 10 and Feb. 23 typhoid fever attacked 8 persons residing in seven households scattered over a wide area covering perhaps 100 square miles of Buckinghamshire and representing entirely different social and economic groups. There was an interval of 8 days between the onset of illness in the two cases in one house—father (Case 4) and son (Case 9)—and it is possible that the one was secondary to the other. Case 3 was an employee in a textile factory owned by Case 4, and Case 9 also worked in the factory. An attempt to recover *Bact. typhosum* from Case 3 (which was confirmed by Widal reaction) failed and she has not been proved

D4, but her close association in time and place with Cases 4 and 9 leaves little doubt that she and they were infected with D4 organisms from a common source. They had all consumed milk from retailer "C." The remaining 5 cases were notified in four different sanitary districts. There was no obvious common factor, and ordinarily they would have been looked upon as sporadic. However, the approximation of dates of onset in all 8 cases appeared to have some significance, and when it was learnt that 6 of them were excreting Type D4 *Bact. typhosum* it became apparent that they in all probability had a common origin. Before they could be typed the cultures from Case 6 were discarded in the clinical laboratory in which they had been isolated; they had nevertheless left their mark, for a laboratory technician who within a material time handled the cultures from Case 6, and from no other patient, developed typhoid (Case 14) due to Type D4.

Cases 13 and 10.—Case 13 was notified in a London borough, and D4 organisms were recovered. A month before this patient became ill she was nursing her nephew, who was an overlooked case of typhoid. This man, although living in London, had worked in Buckinghamshire and had habitually consumed milk from the retailer who supplied Case 8.

Cases 11 and 12.—These cases started simultaneously in the same sanitary district as, but at least 40 days after, Cases 4, 5, and 9. Their homes and places of employment were near together, and although they were unknown to each other they shared a common circle of acquaintances. Apart from "mains" water, no aliment was common to them: one disliked milk, but may have taken a little, uncooked, on her cereal; the other denied drinking milk unboiled, and it could not be established that the milk available to these cases, which came from different retailers, originated in the same remote source. Like Cases 4, 5, and 9, they were both infected with Type D4, and unless we postulate a comparatively wide distribution of this organism, which is improbable, it seems most likely that they were secondary, through some unrecognized intermediary, to the earlier cases in the town.

Case 14.—This patient was the technician who contracted a laboratory infection.

Cases in 1942

Case 15.—This case occurred in Kent a year or more after the events already described, and is included for the sake of completeness. This was another solitary case whose infection is at present unexplained.

Case 16.—This patient lived in Highworth Rural District, Wiltshire. On or about June 20 he began to be ill in his father's cottage, near Swindon. All persons resident in this and the neighbouring cottages gave no serological or cultural evidence of typhoid infection. Later, Case 16 was found to be excreting D4, and it then transpired that until June 8 he had worked daily and had had meals at one of a number of farms in Wiltshire the grouped milk from which had been suspected of being responsible for Cases 2 to 9, in Buckinghamshire, 16 months before. Moreover, apparently sporadic, Case 16, in Wiltshire, began to sicken at the same time as Cases 17 to 21, in Buckinghamshire, and the sole aliment common to all was a particular milk.

Cases 17, 18, 19, and 21.—These occurred almost simultaneously with Case 16, but in an urban district in Buckinghamshire which, so far as is known, had not previously been invaded. These patients included a mother and her daughter; 44 days later a son (Case 22) of this household contracted the disease. The vehicle of his infection was not established, but since D4 organisms were recovered from him it is assumed that the infection survived in the house after the original cases had been removed to hospital. The remaining members of the household showed no serological or bacteriological evidence of infection.

Case 23.—This patient lived within 200 yards of Cases 17 and 19 and developed D4 typhoid 15 weeks after them. Her family consisted of her parents and one brother, and on first inquiry these gave no history of alimentary infection, although the mother was found to be excreting D4 *Bact. typhosum*. The mother's Widal reaction suggested that her infection had preceded the daughter's, and on further inquiry it was found that on June 29 she contracted an illness which is now thought to have been subclinical typhoid. She is therefore included as Case 20, and, like the remaining cases in group 17–21, she had consumed raw milk from retailer "J" at a material time.

The Vehicle of Infection—Milk

It is believed that this story, covering a period of two years, has now been brought to an end as the result of careful investigation of Case 16 at Swindon. The only tangible and continuous thread running throughout the story is the Type D4 organisms in most of the patients. The earlier investigation of Cases 2 to 9 pointed to milk as the vehicle. All 8 patients had been infected simultaneously; they were raw-milk drinkers, and although they obtained their milk from six different retailers, these retailers were all in the habit of receiving supplies from a depot in Hertfordshire, which also provided milk to retailer "A," who supplied Case 1.

There were other considerations which strengthened the suspicion that milk was the vehicle. Case 7 was a tuberculous subject with a pleural effusion and a duodenal ulcer; his diet at a material time was almost exclusively raw milk obtained from retailer "F." Case 6, a member of a large R.A.F. camp, was the only typhoid patient in it. He was peculiar in that he was one of a few men who supplemented their rations by each purchasing a half-pint bottle of milk daily from a milk roundsman, "E." He drank from the bottle.

The Source of Infection

The milk-distributing depot in Hertfordshire supplied about 100 retailers, and in Feb., 1941, received milk from:

Source 1: a large pasteurizing combine depot in London.

Source 2: another large wholesale pasteurizing depot in London, with a subsidiary plant at Swindon. Between Feb. 3 and 13, 1941, milk came direct from the latter plant and was either unpasteurized or flash-pasteurized only. At other times it was satisfactorily pasteurized at the London depot.

Source 3: a group of 20 farms in Buckinghamshire. Some of this milk was delivered raw direct from producer to retailers in the original churns; the remainder passed through the Hertfordshire depot, and may or may not have been bulked and pasteurized there.

Source 4: a group of 13 farms in Wiltshire dispatching raw milk once a day direct by road. The morning's milk of the day of delivery and the previous evening's milk arrived together, but unmixed, in the same consignment at 3 p.m. At material times for the infection of the 1941 cases the evening's milk may or may not have been pasteurized at the depot, but the morning's milk was certainly distributed unpasteurized in the original churns.

The daily turnover of the depot was 2,750 gallons, and the possibility of specific infection having been introduced here was, so far as was practicable, excluded by bacteriological examination of the staff. On first inquiry there appeared to be no way of deciding which of the four contributory sources should be suspected, except on the assumption that pasteurized milk was less likely to be the vehicle than raw milk. Later, during observation of the routine of the retailers, it was noticed that "G," the retailer supplying Case 8, unlike the others implicated during Feb., 1941, called at the depot to collect his supply at 4 p.m. daily and was careful to take churns containing unpasteurized milk recently arrived from Source 4. Retailer "A," supplying Case 1, also collected milk from the depot in his own van; but he was less particular, and might take churns from Sources 1 and 2, but more probably received milk from Source 4, either raw or pasteurized.

Case 2 (retailer "B") presented a serious difficulty in that both the depot and the retailer believed that pasteurized milk from Sources 1 and 2 only had been supplied on this round. The daily quantity at a material time was small—from 10 to 24 gallons; when this amount was 12 or 24 gallons it was convenient that one or two churns of milk from Sources 1 and 2 should be dispatched, but on Jan. 27 and 31 the amounts sent were 10 and 20 gallons respectively, and on these days climatic conditions were such that the milk supplied was in fact unpasteurized and came from Source 4.

The total daily consignment from Source 4 was 900 gallons. In May, 1941, all 13 farms were inspected by the county milk inspector, and four were chosen for special investigation without result. The source of D4 typhoid remained a mystery until Case 16 appeared quite fortuitously, and it was discovered that at the time of his infection he had been working at one of the 13 Wiltshire farms which constituted Source 4. Samples of blood from all seven persons on this farm were examined at the E.P.H. Laboratory, Oxford: five gave negative Widal reactions; that of an inoculated man agglutinated *Bact. typhosum* "H" 1:25 and *Bact. paratyphosum* B "H" 1:25; but the farmer's blood was found to agglutinate standard suspensions of *Bact. typhosum* "Vi" to 1:20, and *Bact. typhosum* "H" to 1:100, and failed to agglutinate the "O" suspensions of *Bact. typhosum* and the "H" suspensions of *Bact. paratyphosum* A and B. He had not been inoculated with T.A.B. vaccine, and these serum reactions suggested a carrier state. Later, Type D4 organisms were repeatedly recovered from his stools over a period of three months, when examination was discontinued. He gave no history of illness simulating enteric fever, and it is not known when he first began to excrete *Bact. typhosum* or whether he had done so continuously or intermittently. In June, 1940, he had developed a cold abscess about his elbow-joint after an injury which did not break the skin. On Feb. 14 and 21, 1941, his doctor attended him in bed for bronchitis and high fever, and on Feb. 19 all the other members of the household had bilious attacks without diarrhoea. A daughter, the dairymaid at the farm, had a cough on Feb. 15, and visited her doctor on Feb. 21, March 8, and March 28. There was undoubtedly sickness in this farmhouse at the time Cases 2 to 9 were appearing in Buckinghamshire, but, since the conjectured date of infection of Case 1 anticipated this period by a month, the probability that the farmer's cold abscess was a manifestation of typhoid cannot be excluded. In an outbreak in Liverpool the carrier responsible suffered from osteitis of the elbow three years before he was identified as the cause of an outbreak (Frazer *et al.*, 1937).

Except when ill the farmer had milked regularly until Aug., 1942, when he was found to be excreting *Bact. typhosum* and action was taken by the local authority which forbade him from participating in the production, distribution, or storage of milk.

Discussion

The preceding account tells how milk from a Wiltshire farm, on which a milker was a persistent carrier of *Bact. typhosum*, gave rise sometimes to a single case and sometimes to small groups of cases of typhoid scattered throughout a wide area of Buckinghamshire and the fringe of Hertfordshire, and how, with one exception, this series included all persons from whom Type D4 *Bact. typhosum* was recovered in England and Wales during 1941 and 1942. Although the organism was not cultured from the milk (which was not examined at the time), neither can it be proved that this particular milk was consumed by the patients; it was undoubtedly available for delivery at material times to the various retailers whose customers developed typhoid. The path for infection was open, although the evidence that infection travelled along this path is no more than circumstantial. All cases arising in Buckinghamshire were investigated. As new cases occurred and were identified and typed as D4 their places in the series became apparent, and the evidence was thereby strengthened. When Case 16 emerged in Wiltshire and led direct to a persistent carrier of D4 organisms with access through milk to consumers 100 miles away, he fitted so closely into a preconceived picture that only by the most unusual chance could his association have been a coincidence.

This story belies the customary conception of a milk-borne outbreak. There was no dramatic explosion of considerable magnitude and with few exceptions the cases appeared to be sporadic. The output of the carrier's farm was 16 to 18 churns a day, all of which had passed through the Hertfordshire depot since April, 1940. Until May, 1941, the milk may have been distributed raw, but subsequently it was reputed to have been pasteurized. The procedure at the depot did not exclude the possibility that an occasional churn escaped pasteurization, but the unusual epidemiological picture suggests another explanation. The events are consistent with the milk having been contaminated sufficiently to cause infection on as few as 4 days in two years, although this number may have been 5, 6, or 7 days, and on one only of these days is there evidence that more than one churn of milk was infected sufficiently to give rise to disease. Such intermittency is more conveniently explained on the assumption that the infection was not introduced direct into the milk during the process of milking by a carrier continuously employed, but that occasional churns were contaminated by polluted well-water used to swill down the farm dairy.

One of the minor lessons to be learnt from this study emerges when Cases 11, 12, 13, and 14 are considered as a group. They were contemporary in onset, and since they were the only detected cases of D4 in the country at the time it might have been conjectured that they were infected simultaneously by a common aliment. In truth they arose from three or even four separate immediate sources linked together by tenuous circumstances to a remote common origin. The fact that at least two of them (Nos. 13 and 14) were secondary cases was established only after prolonged inquiry.

Comment

This paper records one of a number of similar investigations which are in progress, and is by no means a unique example of the way in which phage typing provides links between a series of apparently sporadic cases subsequently proved by circumstances to be associated with a common focus.

The most fundamental objective of epidemiology is to define and render ineffective reservoirs of infection. In the control of an outbreak of enteric fever it is reasonable to give this objective second place and to concentrate in the first instance on the application of those principles of sanitary engineering which have served so faithfully in the limitation of the disease during the present century. The final objective—the elimination of the usual reservoir, the undetected persistent human carrier—must, however, be pursued no less vigorously, but with the deliberation and patience necessary in a process of attrition. The chase should never end with the termination of an outbreak or the implication of a subclinical case conveniently labelled "the carrier."

The true chronic carrier has special qualifications and can almost invariably be recognized by the so-called "Vi agglutination test" (Felix, 1938). Now, by the application of phage typing, he can be identified no less precisely than can the criminal by his finger-print. Moreover, like the criminal, he is apt to leave this "finger-print" at the scene of his crimes, where it may provide a specific clue leading to his detection. It is therefore important that the criminal's "finger-print"—the phage type of the infecting organism—should be obtained from every sporadic patient with typhoid and from a few representative patients in every outbreak. From the preventive point of view, the diagnosis of enteric is incomplete if it rests on a positive Widal reaction only.

In the case of Type D4 the carrier's activities were far from parochial, and his influence was detected in four counties and ten administrative areas during the course of two years. Since infection, like the criminal, does not respect administrative boundaries, there is clearly a need for the equivalent of the Central Criminal Investigation Department. In the matter of enteric infections the way to the finger-print bureau is through the Emergency Public Health Laboratory Service. But finger-prints and phage typing are no more than valuable clues, and the apprehension of the miscreant still depends on the observations and deductions of the field investigators. Without determined field work and the help of what may be a large team of practitioners and medical officers of health mysteries like "D4" are not easily solved.

Summary

The first sustained attempt to apply typing with Vi bacteriophages to a field study of endemic typhoid fever in England is described.

Apparently sporadic cases occurring over a period of two years were traced to a persistent carrier on a farm 100 miles away.

Milk which had passed through a wholesale depot and numerous retail dairies was the vehicle.

I wish to thank team, patients, and carrier for their co-operation, including more particularly Dr. A. Felix and Prof. G. S. Wilson, Emergency Public Health Laboratory Service; and Drs. R. C. Gubbins, W. B. Moore, L. Roberts, and C. E. Tangye, medical officers of health. Dr. J. R. Hutchinson, Senior Medical Officer of the Ministry of Health, directed the field operations. This paper is published with the consent of the Chief Medical Officer, Ministry of Health.

SURGICAL TREATMENT OF OSTEOMYELITIS DUE TO A PENETRATING WOUND*

BY

GEORGE PERKINS, M.C., M.Ch., F.R.C.S.

An almost inevitable sequel to a penetrating wound associated with a fracture is infection of the bone. The inflammation is unlike that caused by a blood-borne organism in that local symptoms and general toxaemia are both less, the probable reason being that from the very beginning there is free drainage from the broken bone. The osteomyelitis pursues one of five courses: (*a*) The inflammation may die down within a reasonable time and never again trouble the patient. (*b*) The inflammation may continue for a long time; let us call this *persistent acute osteomyelitis.* (*c*) The acute inflammation may subside, leaving behind a *sinus*, which extends down into the interior of the bone. (*d*) The inflammation may die down and the wound heal; but later, after an interval of months or years, the acute inflammation recurs. We express this by saying that *the wound has flared.* (*e*) The patient may have a chronic sinus and also be subject to recurrent attacks of acute inflammation in the bone. The problem therefore resolves itself into treating one of four conditions—namely: (1) persistent acute osteomyelitis; (2) a sinus; (3) recurrent acute osteomyelitis (a flare); (4) a sinus with flares.

Persistent Acute Osteomyelitis

In the treatment of persistent acute osteomyelitis we have little to offer surgically. The closed-plaster technique has shown clearly that surgery is not essential to the cure of inflammation. It is true that surgery is of use in acute inflammation—in affording an exit to pent-up pus, as in the opening of an abscess, and in excising *in toto* an inflamed area, as in appendicectomy. And these successes have tended to make the surgeon forget his limitations. In osteomyelitis due to a penetrating wound there is nearly always adequate drainage, and surgery is not required to give an exit to pus. Nor can we hope to excise the whole of the acutely inflamed bone without grossly infecting the surrounding tissues. We are therefore forced to the conclusion that there is no surgical treatment for persistent acute inflammation of bone.

However, although the inflammation does die down at last, it may by its prolongation endanger the life of the patient. Moreover, other disabilities may be present that would render the limb of little use even when the osteomyelitis had subsided: for example, an ununited fracture, an unsuturable nerve lesion, stiff deformed joints, damage to main vessels, wide destruction of skin. In persistent acute osteomyelitis amputation of the limb is therefore often advisable, either to save life or because an artificial limb will be of more use to the patient than his own crippled leg.

A Sinus

The active inflammation of the bone may subside, leaving behind a sinus. A sinus is a nuisance because it condemns the patient to wear a dressing to protect his clothing, and also because the smell from the discharge (particularly if the wound has become secondarily infected by *Bacillus proteus*) is offensive. And patients often clamour for treatment in the belief that a surgeon can easily get a sinus to heal. Sometimes he can; more often he cannot. A sinus indicates either (*a*) the presence of a foreign body or a sequestrum, which the patient is endeavouring to wash out of the wound, or (*b*) the continuation of a mild chronic infection of the bone. And it is often difficult for the surgeon to decide which of these two conditions confronts him. A radiograph gives valuable information because it reveals metallic foreign bodies and often sequestra. It is not decisive, however, for the foreign body may not be opaque (an unabsorbable suture, for example), and not all sequestra are dense.

As a rule a sinus heals after the removal of a foreign body or a sequestrum; and whenever the radiograph shows either, the surgeon should operate. When the radiograph reveals neither, it is justifiable to operate once and once only; for if the sinus recurs, as often happens, further operations are unlikely to be successful. It is important, however, to realize that the type of operation differs in the two cases.

Operation when a Sequestrum or a Foreign Body is Present

The aim of the operation is the removal of the sequestrum or foreign body. A probe is inserted into the sinus and the surgeon cuts straight down (anatomy permitting) on to the point of the probe. If this has entered the bone a small coffin-shaped piece of cortex is removed and discarded, revealing a cavity within which the foreign body or sequestrum is lying. The sequestrum is picked out and the wound is lightly sewn up without drainage. No attempt is made to excise the track or to obliterate the bone cavity. Should the wound later show signs of inflammation the stitches are removed and the wound is allowed to gape. The object of the operation is to remove the cause of the irritation, and if this is achieved the sinus closes.

The question arises—At what time after the onset of the osteomyelitis should one remove sequestra? I believe this should be determined not by the length of time that has elapsed but by the cessation of acute inflammation in the bone. But how are we to know whether the bone is still acutely inflamed? There are so few signs of active inflammation in bone. The radiograph does not help, and providing the products of inflammation are not under tension there is little pain. In fact, the only clinical sign is tenderness of the bone.

---

* A paper read before the British Orthopaedic Association on Feb. 27, 1943.

However, with osteomyelitis due to a penetrating wound there is always infection of the soft tissues as well as infection of the bone; and inflammation of skin, cellular tissues, and muscles can be detected clinically. And we may assume that when the defences of the body have overcome the infection of the soft tissues they have simultaneously overcome the active infection in the bone. If the soft tissues are still inflamed, so is the bone; if the soft tissues are no longer inflamed we may assume that active inflammation has also subsided in the bone. And so, in my judgment, sequestrectomy should be deferred until the soft tissues around the sinus are free of heat, redness, swelling, and tenderness. As soon as the inflammation of the soft parts has subsided sequestrectomy can be safely undertaken. One need have no fear that the sequestrum will not be loose, because, in my experience, sequestra are already detached by the time they are disclosed by radiographs.

Operation when there is no Sequestrum or Foreign Body

In this case the object of the operation is the removal of all infected bone, the assumption being that the sinus exists to give an exit to the products of the continuing inflammation. The plan of operation is entirely different from that of sequestrectomy.

The sinus track is excised and as much of the surrounding fibrous tissue removed as is safe, having regard to the presence of main nerves and vessels. A large extent of bone is exposed subperiosteally, and up to a half of the circumference of the cortex is chiselled away piecemeal until healthy bone is reached. Sometimes the whole diameter of the bone is permeated with chronic inflammatory tissue; if this is so the operation will probably fail, since the aim of the operation—the complete removal of all infected bone—cannot be attained. Care must be taken not to fracture the bone, and the limb should be well supported on sandbags during the operation to minimize the risk. The walls of any cavity should be removed, for unless the soft tissues can fall in and obliterate all dead spaces the operation is unlikely to succeed. The operation entails hard work and much chiselling.

The immediate sequel to the operation is an acute inflammation of the bone that is left, and in order to prevent further necrosis there must be free drainage from the bone. The wound is therefore lightly packed with gauze soaked in paraffin, and this is renewed every few days. The first dressings are painful and should be done under nitrous oxide or intravenous anaesthesia. It is erroneously supposed that the object of packing the wound is to induce it to heal from the bottom, and accordingly the packing is often continued long after it is necessary. The packing is intended to act as a safety-valve so that the tension in the bone does not rise high enough to cut off the bone's blood supply.

The acute inflammation in the bone soon subsides and the safety-valve is no longer required; the packing should then be discontinued. If the packing is continued for too long the soft tissues form a tunnel with fibrous incollapsible walls, and the bone at the bottom remains exposed and is covered with a thin fibrous layer that is always ulcerating.

It sometimes happens that the radiograph shows a foreign body in the soft parts and old osteomyelitis, and the surgeon is not sure whether the sinus is caused by the foreign body or by smouldering inflammation in the bone, and in consequence is undecided which type of operation to perform—whether a simple removal of the foreign body or a resection of the diseased bone. In these circumstances useful information is sometimes obtained by *x*-raying the area after the injection of lipiodol into the sinus: when the opaque track leads to the foreign body it is a safe assumption that the foreign body is the cause of the sinus, and the simple operation is indicated; when the track leads into the bone the bone should be resected.

Recurrent Acute Osteomyelitis (a Flare)

These flares, although associated with local signs of inflammation and often with intense pain, are peculiar in that they are not accompanied by severe or lasting toxaemia. The patient's temperature is raised and he may feel ill; but this phase passes off quickly, and within a few days his health is restored. In this respect a flare is not unlike a bout of malaria.

There is no explanation for these flares and no known method of avoiding them. A patient may not have had any symptoms for years—perhaps 20—then, after a blow or excessive muscular exertion, or sometimes for no obvious reason, the wound flares. The rapidity and ease with which these are overcome show that the body has a strong defence, but seemingly the defence is not strong enough to prevent an attack although capable of smothering it when it occurs. Immunizing the patient with vaccines has not met with any success; indeed, an interesting fact is that once the patient starts having flares he may have several in quick succession in spite of not having had any trouble for years previously.

The inflammation may or may not be confined to the bone. Clinically, the skin, the deep tissues around the bone, or the bone itself may appear to be the principal (or sole) site of the inflammation. Of particular interest is the subcuticular inflammation that spreads far up and down the limb and resembles an erysipelas.

Treatment consists of rest, and the patient should be kept in bed. Locally, hot poultices such as antiphlogistine are soothing. Surgery is not indicated unless an abscess forms. An abscess should of course be opened, but there is no urgency. The longer the abscess can be left the nearer it approaches the surface and the smaller need be the opening. It is sufficient to give an exit to the pus and to leave the wound open; it is not necessary to establish prolonged drainage. As a rule within a few weeks the wound heals, and the patient's condition is then much what it was before the flare. Even when an abscess arises within the bone the bone rarely needs to be touched, because cloacae allow the pus to escape. Only exceptionally, when a high temperature and severe pain persist, is exploration of the bone advisable.

A Sinus with Recurrent Flares

These cases as a rule defy treatment. The sinus indicates a continuous grumbling inflammation, and the flares indicate that the bone is riddled with organisms that are potentially active. Operation rarely does any good, particularly when the ends of the shafts are involved, in which case for anatomical reasons an adequate removal of diseased bone is not feasible.

Most of these patients have undergone many extensive bone operations without any benefit, each one invaliding them for many months. Excluding an operation on the bone, there are two courses open to the patient: one, to accept his lot and to be resigned to periodic flares which will keep him from work for several weeks once or twice a year; and the other, to lose his limb. Luckily the leg is more often the seat of the trouble than the arm, since with a well-fitting artificial leg a man is but slightly handicapped. Many a pensioner of the last war is to-day thankful that he was at last persuaded to have his leg amputated.

When amputation is decided upon it is wise to proceed in two stages. The first amputation is done through the extreme lower limit of the healthy bone, and the skin flaps are lightly held together by two or three stitches. Should the wound become inflamed the stitches are removed and the wound allowed to granulate. Then, when all sepsis has been eliminated, the final amputation is done at the site of election.

The treatment described above is summarized in the following table:

	Bone Surgery	Other Surgery
1. Persistent acute osteomyelitis	None	Amputate if life is in danger or if limb is crippled
2. Sinus	Remove sequestra or excise infected bone	None
3. Flare	(Rarely) drain bone	Open superficial abscess
4. Sinus and flares ..	None	Amputate if a nuisance

J. Schwartzman (*Arch. Pediat.*, 1942, **59**, 466) studied the relation between pallor and anaemia in 943 adolescents with the following results: (1) Of 106 cases of pallor only 22 had true anaemia, while 84 had pseudo-anaemia. (2) 84 cases of true anaemia had no clinical pallor and would not have been detected without the blood count. (3) There was a total of 106 cases of anaemia, or a percentage of 11.3. The male incidence was 2.1% and the female incidence 20.7%. (4) The haemoglobin estimate corresponded to the anaemic state in 98.1%. Schwartzman concludes that routine haemoglobin determinations should be made in all cases regardless of appearance.

TREATMENT OF SCABIES BY T.E.T.M.S.

BY

T. M. CLAYTON, M.B., B.S., B.Hy., D.P.H.

Medical Officer of Health, Blaydon, Ryton, and Whickham Urban Districts

Gordon and Seaton (1942) drew attention to a new preparation (tetraethylthiuram monosulphide—T.E.T.M.S.) which they suggested was worthy of clinical trial, and their experiments on rats infested with itch-mites of the genus *Notoëdres* gave reasonable grounds for assuming that this sarcopticide may give even better results in the treatment of human scabies than either dimethylthianthrene or benzyl benzoate preparations. Percival (1942) has demonstrated that a 5% solution was curative in 50 consecutive hospitalized or ambulatory cases, but that in 0.25% strength the results were much less satisfactory.

The preparation used in the following series of cases was one kindly supplied by Messrs. Imperial Chemical Industries Ltd., and had the following formula: T.E.T.M.S., 25%; polyglycerol ricinoleate, 10%; industrial methylated spirit, 65%. The solution was of a dark yellowish-brown colour and at temperatures below that of the body there was a tendency for crystals of a distinctive yellow colour to form, which, however, were easily redissolved with moderate increase in temperature. The makers recommend that one part of the preparation be added to four parts of water immediately before use and applied twice daily for three days. Force of circumstances, however, compelled deviation from this advice in my original series of cases, so that the 25% emulsion was used in concentrated form, but the results of treatment lead me to assume that a useful purpose was served. About one ounce of the emulsion was sufficient to cover the body surface of an average-sized adult, and it was easy of application, not unpleasant to handle, and without objectionable odour.

Since, at this time, no records were available as to the propensity of the preparation to produce a dermatitis it was considered an advisable preliminary to test the solution, in full strength (25%), on 15 volunteers and as follows:

> The flexor surface of a forearm in each volunteer was vigorously rubbed with warm water and soft soap for three minutes, dried with a towel, and the solution rubbed into the prepared area for a further three minutes and then allowed to dry under atmospheric conditions. This procedure was repeated on three consecutive days, and the volunteers were asked to record any immediate or remote observations. In 2 cases out of 15 a moderate degree of frictional erythema was noted (one a female particularly liable to severe dermatitis on the application of iodine); but this gradually disappeared, and in no case was there the remotest sign of a localized dermatitis during several days' observation—nor was there anything detrimental except that the solution stained the clothing. The stain, however, was easily removed.

After a preliminary test on 4 scabietic patients it was decided to proceed to full-scale treatment of a series of cases with the 25% solution, and in order to give the preparation a stringent trial, patients with severe scabies or severe complicated scabies were chosen. In each case the entire body, with the exception of head and upper neck, was subjected to a uniform method of washing with soft soap and warm water, while a loofah was used for friction in preference to a scrubbing-brush. (The fact that scrubbing-brushes are used in the treatment of scabies seems, in my experience, to deter many of the public from accepting treatment, and I agree with Morris (1908) that "vigour must not be pushed to the length of violence" and am satisfied that such drastic measures are unnecessary in the majority of cases.) The patient was then quickly dried and the monosulphide solution was rubbed thoroughly over the body, particular attention being reserved for the sites most severely affected. In addition, raw or grossly septic areas were dressed with white lint wrung out of the solution. The treatments were for convenience carried out at three- and four-daily intervals by a specially instructed staff of volunteers derived from the personnel attached to a first-aid post where decontamination facilities were available. The patients were requested to bring a clean change of underclothing for use after the final treatment and were advised to sterilize their "cast-offs" and bed-linen by suitable methods. (My experience, however, leads me to the conclusion, like Hebra (1868), Dixon (1941), Mellanby (1941, 1942), and Monro (1942), and unlike Lydon (1941) and MacCormac and Small (1917), that clothing is of decidedly minor importance in the transmission of scabies as opposed to actual and prolonged bodily contact.)

In all cases so treated the results were most heartening, and in some, indeed, remarkable. On presenting themselves for the second treatment several patients or parents made such spontaneous remarks as: "The treatment is marvellous," or "She had the first good night's sleep in weeks." Itching was relieved at once, and the general well-being of the patients improved almost immediately.

TABLE I.—*Details of 14 Patients treated with 25% T.E.T.M.S.*

Case	Sex	Age (years)	Severity of Scabies	Severity of Septic Concomitants	Sites of Maximum Severity	No. of Applications of 25% T.E.T.M.S.	Date of Last Application	Date of Follow-up	No. of Occupants in House	No. of Occupants Affected	No. of Cases Concealed in House	Remarks

In the limited series of 14 cases detailed in Table I it will be noticed that younger patients predominate, yet, in spite of several applications, no sign of dermatitis developed on these supposedly tender skins. Moreover, it was apparent that some of the secondary pyodermatitic concomitants of scabies appeared to be very favourably influenced by the monosulphide dressings. It was also noted that there was a tendency for the preparation to sting on contact with some of the more exposed lesions.

A follow-up of patients in from three to six and a half weeks after treatment showed three cases of apparent reinfection, since in Case 1 there was deliberate concealment of infestation in

other adult members of the family, while Cases 10 and 11 were probably reinfected from next-door neighbours, whose infestation had not then come to notice. It will be noted that in two other cases (Nos. 9 and 14) in which there was concealment recurrences occurred at a much later date.

From Aug., 1942, onwards a second series of scabietic cases were treated with a 5% aqueous preparation of the 25% emulsion. On the addition of water an interesting bright-yellow suspension was formed, and it was found that not only was it essential to prepare the medicament immediately before use but that warm water as a diluent was superior to cold water, since the sediment which invariably formed upon the bottom of the vessel was less bulky. Such a 5% preparation, allowed to stand overnight, produced a substantial gritty deposit and rendered the solution unsuitable for application to the skin. In the series of 93 cases treatment was in some instances performed daily and in others every other day, whilst a similar method of routine was practised as before.

So far as could be ascertained, none of the cases treated had received prior medication; neither were directions given by me regarding the desirability of sterilizing or fumigating clothing and bedding during or after treatment. Table II shows the relevant details.

Analysis of Table II

Of 93 cases treated and subsequently visited on the first of two "follow-ups" (74 not less than one month and 19 in from two to four weeks after the last application of T.E.T.M.S.) none showed any sign of recurrent scabies. A second "follow-up" not less than one month after the last application showed 6 cases suffering from early scabies (Nos. 17, 18, 42, 44, 75, and 78), and of these only one case (No. 78, who showed a few minute papules and vesicles on one hand) had received her first "follow-up" under one month—i.e., 22 days. Since Munro (1919) has indicated that the life-cycle of the parasite, egg-to-egg stage, varies between 9 and 15 days (and there is much extraneous support for his findings), it is reasonable to conclude that none of the 6 recalcitrant cases could have been recurrences in the true sense, but rather reinfections. It can therefore be stated with some degree of certainty that the entire series of 93 cases were cured, but that 6 were reinfected from a concealed familial source. Further points which appear from the analysis are:

(*a*) An approximate average of 3 applications were needed, although in some cases 6, 7, and 8 applications were deemed necessary. From 6 of the later cases, acting as a small test group, active female itch-mites were extracted before treatment with 5% T.E.T.M.S. Twenty-four hours later further samples were extracted, and in 4 cases the parasites were found to be dead; while a further application had killed additional specimens taken from the remaining 2 cases twenty-four hours later still.

(*b*) From 227 occupants in the houses concerned 154 (67.8%) cases of scabies were discovered.

(*c*) Of 93 patients treated 88 slept with infested bed-partners, while the remaining 5 were of school age and associates of scabietics or living in the same house with them.

(*d*) Out of the 93 patients 55 lived in houses having a slipper bath with an adequate hot and cold water supply.

(*e*) Of the 93 cases 7 produced a mild erythematous dermatitis, which was found to be of little moment and quickly subsided on discontinuing the treatment. The rash was usually most obvious on the upper chest and shoulders. It is of interest to note that in the first series treated with the 25% emulsion no sign of dermatitis was apparent, and this would seem to be due to the oily and more penetrating character of the soluble T.E.T.M.S., as opposed to the watery 5% suspension.

From these results, and in my experience generally, routine fumigation and sterilization of clothing and bedding have limited value, besides being expensive. Reasonable cleanliness of person, clothing, and household is calculated to give equally good results.

Comment

It is stressed that the original cases were on the whole, and of their type, severe and responded extremely well to treatment. It is suggested that the application of the 25% emulsion, though seemingly wasteful, may be found both useful and time-saving, especially in severe and complicated cases for which hospitalization is considered necessary and when available beds are at a premium. Furthermore, it is admitted that in the first series of cases treatment erred on the generous side, and experience may show that the number of applications of the 25% emulsion may be reduced without detrimental effects. Alternatively, it is suggested that a similar emulsion with a smaller percentage of combined T.E.T.M.S. may perhaps give comparatively good results.

In 5% aqueous solution the preparation was less spectacular, though of considerable potency, and the dermatitis recorded in 7 cases was of a mild order. My observations, bearing in mind the limitations of the series, stimulate a cautious yet hopeful opinion that T.E.T.M.S., used under adequate supervisory control, may prove a potent and convenient acaricide and be preferred to other sulphur compounds. In conclusion, I would stress that it has not been my intention to detract from the merits of benzyl benzoate, for which I have high regard.

Summary

T.E.T.M.S. in 25% emulsion has been found to be curative in 11 out of 14 cases of severe and complicated scabies, the remaining 3 cases being probable reinfections.

In 15 volunteers and 18 patients the emulsion failed to produce dermatitis or irritation beyond a preliminary smarting in some severe cases.

It would appear to have extremely beneficial results upon some of the secondary concomitants of scabies.

In 5% aqueous solution it has proved curative in 93 consecutive cases and produced only mild dermatitis in 7 patients.

It has proved to be a sarcopticide of potency against the human itch-mite and is worthy of extended trial.

Thanks are extended to Messrs. Imperial Chemical Industries Ltd. for generous supplies of tetraethylthiuram monosulphide and, in particular, to Dr. C. M. Scott, whose kind co-operation was much appreciated.

ON THE VALUE OF VITAMIN B_1 IN PREVENTION OF TOXAEMIA OF PREGNANCY

BY

F. J. BROWNE, D.Sc., M.D., F.R.C.S.Ed., F.R.C.O.G.

Professor of Obstetrics and Gynaecology, University of London;
Director of the Obstetric Unit, University College Hospital

This experiment was suggested by perusal of the last (1940) Annual Clinical Report of the Department of Obstetrics and Gynaecology of the University of Hong Kong, in which Gordon King reported 155 cases of avitaminosis B_1 (beriberi) complicating pregnancy and labour, 117 (75%) of which had a blood pressure of 140/90 or over, including 16 cases of eclampsia. Assuming that the usual incidence of eclampsia is 1 in 500, it is apparent that its incidence in beriberi is increased about 50 times. Other observations pointed in the same direction, though less definitely. Siddall (1938), impressed by the high incidence of pre-eclamptic toxaemia and eclampsia in Canton, where beriberi is endemic, believes that B_1 deficiency in pregnancy leads to a malignant hyperfunction of the pituitary, with disturbed carbohydrate metabolism, oedema, and raised blood pressure. Nixon, Wright, and Fieller (1942) investigated the vitamin B_1 content of the urine, and in certain cases also of the placenta, in 46 clinically normal and 60 abnormal pregnant women whose disabilities were as follows: hypertension 28, hyperemesis 6, pre-eclampsia 3, eclampsia 9, oedema 14. They concluded that in eclampsia the amount of vitamin B_1 excreted in the urine and concentrated in the placenta was significantly lower than in the normal cases. In none of the other clinical groups, however, did the amount of vitamin B_1 differ significantly from the normal. Ross *et al.* (1938) added dried milk, vitamins (including vitamin B in the form of yeast tablets), calcium, and iron to a diet which, for pregnant women, might be regarded as marginal in regard to protein, vitamins, and minerals, but did not find any significant effect on the incidence of toxaemia. Twenty-seven patients were given the enhanced diet, and 9 (33.3%) became toxaemic, while among 26 controls 11 became toxaemic (42.3%). The women were all resident in a charitable institution, and their diet could therefore be carefully supervised.

The Present Investigation

In the autumn of 1941 an investigation was started in which vitamin B_1 was given to 100 women who were not more than 20 weeks pregnant, and continued till term. Alternate cases were taken as controls. To the treated women 1 tablet containing 3 mg. of vitamin B_1 (aneurin hydrochloride) was given daily. As each milligramme represented 320 I.U. of B_1 the total daily dose given to each patient was 960 I.U. In course of the investigation a certain number of patients dropped out through various causes—miscarriages, removals, etc.—so that in the end there were left 169 women, consisting of 88 treated cases and 81 controls.

Results.—In assessing the incidence of toxaemia in the two groups two different standards of toxaemia are taken: (1) a blood pressure of 130/70 (standard I); (2) a blood pressure of 140/90 or over, or any blood pressure of over 130/70 if accompanied by albuminuria (standard II). Of treated cases there were 32 (36.3%) who had a blood pressure exceeding 130/70, excluding patients with chronic hypertension. Of the control cases 20 (24.6%) had a blood pressure of 130/70. Of treated cases there were 7 (7.9%) who had a blood pressure of 140/90 or over, or a blood pressure of over 130/70 with albuminuria. Of the controls there were 4 (4.9%) who were toxaemic according to this standard. The results may be made clearer by the following table:

Table showing Incidence of Pre-eclamptic Toxaemia in Treated Cases and in Controls

	No. of Cases	Incidence of Toxaemia	
		Standard I	Standard II
Treated	88	36·3%	7·9%
Controls ..	81	24·6%	4 9%

These negative results might be explained in one of two ways: first, that B_1 deficiency does not play any part in the causation of pre-eclamptic toxaemia; secondly, that the diet of the women included in this experiment was not deficient in vitamin B_1. In this connexion it may be noted that McCance and co-workers (1938) in an investigation of the diets of 120 women from 3 to 9 months pregnant, at varying income levels, found that all, even including those in the higher-income groups, received suboptimal amounts of B_1, the estimated daily intake varying from 209 to 454 I.U., as compared with an optimal intake of 600 to 900 I.U.

The conclusion to be drawn from this experiment is that, so far as the prevention of toxaemia of pregnancy is concerned, no beneficial effect is obtained by supplementing the diet with vitamin B_1.

I am much indebted to Glaxo Laboratories, Greenford, Middlesex, for their interest in the experiment, and for a free supply of vitamin B_1 tablets.

Medical Memoranda

Intra-uterine Rupture of the Umbilical Cord

The following case occurred recently in my practice, but I can find no record of a similar happening in England, although a few instances of spontaneous rupture have been recorded from other countries. Most of those already reported involved interference in an abnormal confinement or abnormalities of the cord.

Case History

The patient, aged 28, had had one previous normal confinement. The present pregnancy was normal except for some anaemia, and later there had been suprapubic pain for which no cause was found. She went into labour at term at 8 a.m. and had mild pains for ten hours. I saw her early in labour; the head was engaged, the foetal heart normal, and pains infrequent and slight. The nurse visited during the day and there was no advance. At 7.20 p.m. the nurse saw her again; pains were more frequent, but she left the house. At 8.20 p.m. the patient suddenly had one severe long pain. At this time she felt the foetus give a violent kick; she lost a small amount of blood per vaginam and felt faint. After this time a little blood was lost with each contraction, but on no occasion was the loss profuse. The nurse arrived at 8.40 p.m. and sent for me immediately. There had been slight loss of liquor amnii, but at 8.50 p.m. the membranes ruptured; there was a large amount of liquor, and the foetus followed at once. The cord was seen to be ruptured. The maternal end of the cord presented immediately afterwards; there was no bleeding from either foetal or placental end. The foetus was asphyxiated; it made no attempt to breathe, and there was no apex beat palpable. It was an apparently healthy full-term male, but remained blue in colour and flaccid. The placenta and membranes were delivered intact five minutes afterwards. The puerperium was uneventful.

The placenta was rather pale in appearance. The cord was 24 in. long and was torn about 1/4 in. from the umbilicus. There was just enough stump to hold a clamp. It appeared normal except at the umbilical end, where it was swollen and looked rather sloughy. The vessels themselves were not swollen. The tear was transverse and irregular. The amniotic sac contained some meconium and a blood clot which did not look very recent.

Discussion

A case of this sort in an otherwise normal confinement must be exceedingly rare. It is difficult to see why a cord of normal length should rupture. In this case there was no relative shortness, as the cord was not round the neck nor was there any sign that it had been so. In other reported cases there have generally been intra-uterine manipulations or relative or absolute shortness of the cord, which generally ruptures near the placenta although the cord is often thinner just at the umbilicus. The cord is said to be able to withstand a stress of 9 lb. It has been suggested that a loop of cord may get fixed at the place of looping. During the advance of the foetus there may be enough stress produced on the fixed cord to cause rupture. In this case there was some abnormal stimulus to the foetus, causing abnormal activity half an hour before delivery. This was at the time of the severe pain and the violent kick of the foetus, which was the last movement felt by the mother. Unfortunately there was no one present to record the foetal heart rate. The loss of blood was never excessive. The foetus undoubtedly died from asphyxia and not from haemorrhage. Bleeding from the foetal end would soon cease as the heart's action would be speedily inhibited by on-coming asphyxia. Bleeding from the maternal end would soon cease from retraction of the torn ends of the vessels. There was no evidence of retroplacental clot or earlier separation of the placenta to cause the external haemorrhage. This was therefore presumably due to uterine contraction expelling a small amount of blood from the torn ends of the cord into the amniotic sac. Some of this blood then escaped with the leaking liquor; the rest remained as a clot in the sac.

I would like to thank Dr. J. R. Campbell Canney and Dr. G. E. R. Hamilton for their help with this article.

B. Rose and J. S. L. Browne (*Ann. Surg.*, 1942, **115**, 390) found that in some patients after severe burns there was a large increase in blood histamine. In all cases there was a decrease in the blood histamine with the appearance of toxaemia and oedema. As the oedema and signs of toxaemia disappeared and the patient improved, the blood histamine rose to normal or higher levels.

EYESIGHT

The Practice of Refraction. By Sir Stewart Duke-Elder, M.D., F.R.C.S. Fourth edition. Churchill's Empire Series. (Pp. 328; illustrated. 15s.) London: J. and A. Churchill. 1943.

The Practice of Refraction, by Sir Stewart Duke-Elder, of which a fourth edition has just been published, is a book dealing with a subject of the highest importance, and in such excellent fashion that it will be one of those works which will be of value to graduates studying eye-work, and also to ophthalmic medical practitioners. Every one of us, no matter how keen our thought and work, gets an extra stimulus from the written experience of another.

At no time in our history has the best eyesight been of such high importance to the nation. Both for men and women on service in all the Forces, and particularly in the air and at sea; and for the vast numbers who are employed in industrial factories doing fine close work for hours every day—the better their vision the better their work. The more accurately the eye doctor measures errors of focus, and the more nicely he corrects the errors with glasses, the swifter and the finer will be the work of each of these people. A book such as this of Duke-Elder is particularly good, because it stimulates the mind of the eye student and the doctor, and tends to make him explain to his patient the conditions found by plain words, and also by sketches, that give the patient a clear understanding of the state of his eyes.

Alas, that there should be even in these days some, who are deemed "educated," who persuade themselves and try to persuade others that poor sight, mostly arising from anatomical defects with which they were born, may be diminished or removed by fantasies of imaginative persuasion. Even with squint, as Duke-Elder writes, "so disfiguring is this effect that the condition of squint has been recognized from the earliest times, and its history is full of interesting sidelights. It was—and still is—considered an affliction sent by an angry god, and the ill luck brought by the look from a cross-eyed person forms the basis of many legends." Maybe these folk are so fantastic that they would persuade themselves that a snub nose is really a Wellington nose! For the differences between so-called "far-sight," and "short-sight," and "astigmatism" are as sharp and physical as our nasal features.

At the end of the book is Appendix VI, which gives a full and accurate statement of "official visual requirements" for all forms of service; these are of great value to-day.

This new edition bears no marks of wartime limitations. The paper, the print, the illustrations, and the binding are all good.
